It does not belong to this section to describe the previous steps necessary for silvering, as grinding, polishing, &c., these will be treated of in glass making, and glass grinding; our present business is simply to explain the process of silvering, particularly by means of the Machine described below, which was presented by Mr. Farrow to the Society of Arts, and for which he was rewarded by their large silver medal. See *Trans. Society of Arts*, vol. xlix. According to the former practice, a thin blotting paper was spread on a table or slab of marble, and sprinkled with fine powdered chalk, and this done, over the paper was laid a thin lamina of tinfoil on which mercury was poured and equally distributed over the foil with a hare's foot or cotton. Over the leaf of tin was laid a very thin and smooth kind of paper, and over that the glass plate, then with the left hand the glass plate was pressed down, and with the right the paper was drawn gently away. The plate was then covered with weights and the superfluous mercury driven out; heavier weights were then added, and the plate remained till it became dry, when the glass was complete. But in the more modern practice the common silvering table is a slab of stone ground to the most perfect degree of evenness, and placed in a frame so that a certain degree of obliquity can be given to it. All round the margin is a gutter, through which, at one corner, a hole is made, so as to allow the escape of the mercury when the plug that closes the hole is removed. It is this corner which is lowest when the oblique position is given to the table, in order that the mercury may be run to it from the other parts of the gutter. On the silvering table is spread a sheet of tinfoil of the same size as the glass, or rather a little larger; a fluid amalgam of tin is then poured on it, and spread over its surface with a brush till it adheres; more mercury is then poured on, till it stands about a quarter of an inch deep over the tinfoil. The plate of glass being previously made quite clean, is then slid gently and steadily from a sheet of paper, just dipping below the surface of the mercury, but avoiding to touch the tinfoil for fear of tearing it. When the glass is fairly over the tinfoil, the table is placed a little oblique by means of a rack, the mercury now runs into the gutter, and the glass subsides on the tinfoil. The whole surface of the glass is then covered with leaden seven pound weights, having cloth at the bottom; by this pressure, at the end of twenty-four hours, the silvering is so firmly adherent to the glass, that the weights may be removed, and the glass raised up in a sloping position, to allow the mercury to drip off till the silvering has become quite hard.

Mr. Farrow's improvement consists in dispensing

Manufactures.

Mr Farrow's silvering Machine.

Pl. xxxv.
Fig. 3, 4, 5.

with the loose leaden weights, and in producing the required pressure by means of screws. It is attended with the following advantages. First, all hazard of breaking the glass during the application of the pressure is avoided; when loose weights are used, one will sometimes slip out of the hand of the workman, and falling on the glass will break it. Secondly, the plate, as soon as the pressure is made by means of the screws, can be tilted up even in a vertical position, so as to expedite considerably the drip of the mercury from the silvering; an operation which is manifestly impossible where loose weights are employed. Mr. Farrow himself has hitherto applied this invention only to small plates for dressing-table glasses; but Mr. Wheeler, a manufacturer of looking-glasses, has applied the apparatus, with some modifications, to plates 47 inches long and 29 inches wide.

In plate xxxv. fig. 3 is a section of the Machine; *a b* the stone slab; *c d* its frame, containing the usual channel for the mercury; *e* one of the end supports, on which the bed can turn, for the purpose of being tilted; the middle strengthening bar *f*, which serves for an axis, is placed a very little on one side, to make the side *d*, at which the slope is given, always preponderate, that side usually resting on one or more screws, by which it is lowered or raised again. The dotted lines in fig. 3 show that side of the bed as lowest and resting on a small block. The upper and under sides of the frame *c d* are made quite parallel, to fit the hooked ends of the long clamps *g g*, which slide from one end to the other. The clamps are furnished with little plates *h h*; these project inwards for the clamps to stand and slide on when the screws are loosened. They are also, with the under hooks, made sufficiently wide, as shown in the end view, fig. 4, to prevent the clamps from falling on one side. A sufficient number of these clamps are provided to range over the bed about one foot apart; and the screw holes in one clamp are made to be opposite the intervals in the next, in order to distribute the pressure more equally over the surface of the glass; *i i i* clamping blocks of wood faced with leather; they hang on the screws loosely, so as to rise and fall with them and allow of being placed in any position. They are about seven inches long, and the screws are eight inches apart. The clamps are usually all drawn to one end of the bed, to be out of the way, and to make room for the glass plates being slid on, and need only be taken off when the largest glass is to be silvered, and then replaced to give the pressure.

Fig. 5 is an end view, or elevation, of a portable bed for silvering small glasses, and is Mr. Farrow's original invention; it has wooden sides *k k* rising above the bed, in which the several wooden clamping bars *g* slide. Here two screws only are used to each bar; and the battens that hang on their lower ends are in one piece. This, with the glass on it, is placed by hand in any required position. The glasses being quite clean for silvering, the faces of the battens or clamping blocks *i i i* never take any dirt whilst in use; and as they always remain pendent, with their faces downwards, when out of use, they keep clean, so that the glasses are not liable to any scratches from them.

Silvering glass globe.

(451.) In the *Philosophical Transactions*, No. 245, a method of *foliating* globe looking-glasses is given, communicated by Sir R. Southwell. The mixture is quicksilver and bismuth, of each three ounces, and tin and lead, of each half an ounce; to the last throw in the marcasite, and afterwards the quicksilver; stir them well

together over the fire; but they must be taken off, and be towards cooling before the quicksilver be put to them. When the mixture is used, the glass should be well heated, and very dry; but it will do also when it is cold, though best when the glass is heated.

Mr. Boyle's method, which he prefers to any which he ever met with in print, is this: take tin and lead, of each one part, melt them together, and immediately add of good tin glass, or bismuth, two parts; carefully skim off the dross; then take the crucible from the fire, and before the mixture grows cold, add to it ten parts of clear quicksilver, and having stirred them well together, keep the fluid in a new clean glass. When every thing is prepared to use, first purge it by straining it through linen, and gently pour some ounces into the glass to be foliated through a narrow paper funnel, reaching almost to the glass, to prevent the liquor from flying to the sides. After this, by dexterously inclining the glass every way, endeavour to fasten it to the internal surface; which done, let it rest for some hours; then repeat the same operation, and so continue at times, till the liquor is slowly passed over, and equally fixed to the whole superficies; which may be discerned by exposing the glass to the eye between that and the light.

(452.) *Sowing and threshing Machines* are used in agriculture for the purposes indicated by their respective names. Of these the sowing Machine is much more ancient than the latter, which is the invention of only the last century; whereas it appears from Beckmann's *History of Inventions*, that sowing Machines were known so early as the XVIth or beginning of the XVIIth Century, but the invention, he says, is not of English origin. Locatelli, a German, of whom, however, very little is known, is commonly considered as the inventor; and it is stated that experiments were made with a Machine of this kind by order of the Emperor of Germany, before a Commissioner appointed for the purpose, and were so successful that the inventor was rewarded by the Emperor, and sent with a letter of recommendation from him to the King of Spain. The small Tract in which this statement is recorded has no date except a written one on the title-page, which, if correct, brings the invention back to the last year of the XVIth Century, in the reign of Rodolphus II., who was much attached to mechanical inventions and pursuits.

In 1669, Evelyn gave to the Royal Society of London a complete description of Locatelli's invention; where it is also stated that, in consequence of the success attending the experiment in Germany, the inventor went to Spain, and proved by public experiment the advantages of the Machine. Locatelli published a small Work in Spanish, descriptive of the engine and its advantages. This was dedicated to Geronimo de Camargo, who was ordered by the King to make known and promote the application and sale of the Machine, the right of which was secured to the inventor by patent at a fixed price; and it appears that in 1664 great numbers of them were sold in Madrid.

The construction was exceedingly simple. The seed box, the cylinder of which was supplied with two small wheels, required only to be hooked or fastened, by means of ropes, to the end of the plough; it is, however, very inferior to the drilling Machine or drill plough of the present day; we do not therefore stop to describe it, particularly as the subject itself seems rather to belong to Agriculture than to Mechanics.

(453.) *Threshing Machines*.—These are a class of Ma-

Machinery.

Sowing and threshing Machines.

Manufac-
tures.
Threshing
Machines.

chines, the policy of introducing which as a substitute for the operation of the flail has been much questioned, and has given rise to various arguments, and to some disturbances in our agricultural districts. On general principles there can be no doubt that the farmer has equal right with the manufacturer to introduce any description of Machine which will enable him to produce his grain and bring it to market at the lowest price, as a benefit is thus ensured not only to the Agriculturist but to the Public generally. The question is therefore, whether it does cost the farmer less to use the threshing Machine or the flail. The former would undoubtedly be the cheaper if at the same time the labourer could be employed; but in too many instances where horses are employed in driving the threshing Machine, the labourer is idle and fed as a pauper at the expense of the parish; and in this point of view, the policy of employing mechanical means as a substitute for manual labour is certainly of a very questionable character. Still, however, it has been an object for many years past to introduce Machines for the purpose of threshing corn, some of which have been driven by wind, others by water, but more commonly by horses. According to Dr. Gregory, in the second volume of his *Mechanics*, the first threshing Machine dates its origin in 1732, having been constructed by a millwright in Edinburgh of the name of Menzies. It consisted, as far as can now be ascertained, of several parts resembling flails, which were attached to a movable beam, and inclined to it at an angle of about ten degrees. On each side of the beam were placed floors or benches, on which the sheaves were spread, and by the action of a crank attached to the beam, the flails received their motion, making each about thirty strokes per minute, whereby the corn was detached from the straw in a manner very much resembling the operation of a common flail in the hands of a farmer's labourer.

The next Machine of this description on record is also of Scottish origin, the invention of a Mr. Stirling of Dumblane; this was not completed till 1758. It was driven by a water wheel, having an inner wheel furnished with forty-eight cogs; turning on the same axle with this cog wheel was connected a vertical pinion or trundle with seven staves and the axle of which passed through a floor above the wheel, its upper pivot having been secured in a beam six inches above the floor. At the height of three feet three inches from the latter, two straight pieces of squared wood (each four feet in length) were inserted through the axle of the pinion, at right angles, so as to form four arms which moved horizontally. To the end of these arms were fixed four iron plates, each twenty inches in length, and eight inches in breadth at the extremity nearest to the arms, but tapering to a point at the opposite ends.

The horizontal fly here described constituted four threshers, which were inclosed in a cylindrical wooden box three and a half feet high, and eight feet in diameter; on the top of this box was an opening eight inches in width, extending a foot and a half from the circumference towards the centre, through which the sheaves of corn descended; the latter having been previously opened, and laid separately on a board provided with two ledges, gradually declining towards the opening; within the cylindrical box there was an inclined plane, along which the straw and grain fell into a wire screen or riddle two feet square, which was placed immediately beneath a hole of a similar size; the screw was jerked

at each revolution of the spindle, by means of a knob fixed on its side, and was thrust backwards by a small spring which pressed it in a contrary direction. Thus the short straw, together with the grain and chaff which passed through the wide screen, fell into an oblong straight riddle, one end of which was raised and the other depressed by a similar contrivance; and as that last mentioned was not provided with a ledge at the lower end, the long chaff which could not pass through dropped thence to the ground, while the grain and smaller chaff descended into a pair of common barn fanners, and were thus separated with great exactness. These fanners were moved by means of a rope which ran in a shallow groove cut on the circumference of the cog wheel. In the mean time, the straw collected in the lower part of the box over the wide riddle was drawn down to the ground through an opening two feet and a half square with a rake, by persons employed to form it into trusses.

Some other Machines for the same purpose were also projected and executed about the same time, one of which is described by the author above quoted, but the first completely useful threshing Machine was not constructed till 1785. This was the invention of Mr A. Meikle, whose ingenuity has been already recorded in the article Wind-mill. This Machine might be driven by wind, water, or horses, by the usual means already described under our article Mills. Supposing, therefore, the first rotation obtained, the essential part of the threshing Machine may be described as follows. On a sloping or inclined board or plane at one extremity of the Machine, the sheaves of corn (being first opened) are spread by an attendant; at the bottom of the plane are two fluted cast iron rollers of about three and a half inches diameter, which are made to revolve about thirty or forty times in a minute in opposite directions, which of course carry the corn and straw between them into a close casing within which is a horizontal hollow drum of about three and a half feet diameter also in rapid rotation. On the circumference of this drum and parallel to its axis, are fixed four leaves of wood each armed on one side by a thin projecting streak of iron. These leaves pass within about an inch, or less, of the iron rollers above named, and as the corn and straw pass through them, these by their action separate the corn from the straw, throwing it through an opening on its further side with considerable force, but it is prevented from flying away by another wooden casing above; it therefore falls down below upon a concave wire bottom or screen, through which the corn and small chaff fall into a hopper of which this screen forms the concave top. In the cylindrical space above the wire screen last mentioned, two cross arms revolve, carrying at their extremities rakes with teeth four or five inches in length. These collect together the straw and long chaff from which the corn has been extracted, and cast it out at an opening still further removed from the front of the Machine. The fanners above mentioned, by their operation at the lower part of the hopper, drive away the light and short chaff, and the corn which remains in the space below is generally considered fit for market.

The preceding description will be better understood by Pl. xxxiii. references to plate xxxiii., where N, fig. 5 and 6, represent the main axle of the Machine, which may of course receive its rotation from any first mover. On this axle in the particular Machine in question, is fixed the wheel DD, which carries 84 teeth and drives the pinion b of 24 teeth placed upon the axle b k. Upon the same axle

Machinery

Manufactures.

the wheel E E revolves carrying 66 teeth, which drive the pinion c of 15 teeth, and consequently the threshing-drum x x, which is fixed upon the same axle. The feeding rollers r r are driven by the intervention of the three toothed wheels h, e, d, the latter of which is fastened on the axis of the upper feeding roller. The wheel h upon the gudgeon h b contains 24 teeth, to act on the intermediate wheel that drives d containing 22; but when the fluted rollers require a greater velocity, e is taken from its iron axle, and a greater or less wheel substituted in its room. The short axle l m is furnished with a pulley p, which by means of the leathern belt or rope p p gives motion to the fanners placed below the threshing screen and straw shaker K K.

Fig. 6 represents a plan of the wheels, threshing drum, and straw-shaker, where the corresponding parts in fig. 5 are marked with similar letters. The wheels D D and h convey motion to the straw shaker, the largest one, D D, is fixed on the axis N, and carries 84 teeth, and drives the other which contains 14 teeth, which is placed upon the axis of the straw-shaker K K.

In this figure the straw and corn which are not seen in fig. 5 are represented on the feeding board at S where it meets with the fluted rollers r r, by which it is drawn into the closed case above referred to, and is exposed to the action of the four leaves w w of the threshing drum; here a great deal of the corn is separated from the straw and falls down below, while the straw and chaff containing still some corn, is thrown forward through a hole into another close case and is then subject to the operation of the straw-shaker K K.

Various threshing Machines are constructed, and a still greater number have been proposed which never were constructed. The reader who is curious to see some of the former may consult Gray's *Complete Millwright*; *The Repertory of Arts*, vol. lviii. and lix.; Gregory's *Mechanics*; Ferguson's *Mechanics* by Brewster.

Quantity of corn threshed.

(454.) The quantity of corn which a Machine will thresh in a given time, depends so much upon the judicious formation and position of its parts, that one Machine will often perform double the work of another, though constructed upon the same principles, and driven by the same impelling power. Misled by this circumstance, those who have given an account of the power of their threshing mills, have published merely the number of bolls which they can thresh in a given time, without mentioning the quantity of impelling power, or the number of horses employed to drive them.

Mr. Fenwick, whose labours in practical Mechanics we have already mentioned with commendation, has furnished us with some important information upon this point. He found, from a variety of experiments, that a power capable of raising a weight of 1000 pounds with a velocity of 15 feet per minute, will thresh two bolls of wheat in an hour; and that a power sufficient to raise the same weight with a velocity of 22 feet per minute, will thresh two bolls of the same grain in an hour. From these facts, Mr. Fenwick has computed the following Table, which is applicable to Machines that are driven either by water or horses.

TABLE of the Power of Threshing Machines.

Machinery.

Gallons of water per minute, ale measure, discharged on an overshot wheel 10 feet in diameter.	Gallons of water per minute, ale measure, discharged on an overshot wheel 15 feet in diameter.	Gallons of water per minute, ale measure, discharged on an overshot wheel 20 feet in diameter.	Number of horses working 9½ hours each day.	Bolls of wheat threshed in an hour.	Bolls threshed in 9½ hours actual working, or in a day.
230	160	130	1	2	19
390	296	205	2	3	28½
528	380	272	3	5	47½
660	470	340	4	7	66½
790	565	400	5	9	85½
970	680	500	6	10	95
1	2	3	4	5	6

The first four columns of the preceding Table contain different quantities of impelling power, and the two last exhibit the number of bolls of wheat in Winchester measure which such powers are capable of threshing in an hour or in a day. Six horses, for example, are capable of threshing 10 bolls of wheat in an hour, or 95 in the space of 9½ hours, or in a working day, and 680 gallons of water discharged during a minute into the buckets of an overshot water wheel 15 feet in diameter, will thresh the same quantity of grain.

(455.) *Tube drawing Machines.*—Brass tubes are drawn in two different ways; in one of which the tube is drawn through the gauge, and in the other the gauge is drawn over the tube: the former is generally employed in drawing small tubes, and the latter for the larger kind of tubes. The power employed also in the former being comparatively small, is generally manual strength applied to a system of wheelwork to increase the power, the other is commonly effected by some other first mover.

Drawing brass tubes

The brass or copper tube being first cut of a proper breadth out of a sheet of the metal, is bent round a cylinder into the tubular form, and the two edges securely brazed. A treble is then taken whose external diameter is equal to the internal diameter of the intended tube; the size of the treble or cylinder on which the tube is first bent up is always larger, so that the rough tube passes over the treble on which it is to be drawn quite freely: this latter, which is a solid steel cylinder, is very truly turned in a lathe, except that one end is rather tapering. The tube is placed over this, and is battered over the small end of the treble so as to allow the treble and plate to pass through the gauge or gauge plate. Then when the former of the two methods of drawing is employed, the end of the treble and tube is seized by a strong vice or pair of nippers, and the gauge plate being securely fixed in a frame, the drawing power is applied and the tube and treble are thus forced through the gauge, the tube stretching round the gauge plate as it gets compressed in its passage. Having passed through a small blow struck upon the end of the treble, remove it from the inside of the tube. The latter is then placed in a lathe and its rough ends removed by a parting tool, and the tube is com-

Manufactures.

pleted. In the process above described, the drawing is generally horizontal, the barrel carrying the chain is also placed horizontally, which is turned by a winch carrying a fly wheel and proper wheelwork to increase the power.

In the larger tubes the gauge is, as above stated, drawn over the tube instead of drawing the tube through it as in the above; and generally in this case, the drawing is vertical, that is, the treble with the tube is placed on its end vertically, the small end uppermost, and the tube turned over the end, and well battered down about the upper small part so as to allow the gauge to pass over. The drawing power is then applied to the gauge itself, which is drawn over the tube from the top to the bottom, the tube stretching downwards as the operation proceeds.

We have not thought it necessary to give a drawing of either of these Machines, which may easily be comprehended; and of course the nature of the power employed, and of the Machinery for increasing it, are perfectly indifferent to the operation, so that there be sufficient power for the purpose.

Sometimes, both for cheapness and for strength, a tube of iron is covered with a brass tube instead of being all brass. In these cases the brass tube is drawn over the iron tube, the latter being placed over the treble, which being removed, the brass remains in contact with the iron, and forms with it externally a perfect tube or cylinder of brass.

Reed-making Machine.

(456.) *Machine for making weavers' reeds.*—In the operation of weaving, the several threads of the warp are passed through an apparatus to keep them spread to their proper breadth, and which is also used for driving up each successive thread of the waft to its proper degree, according to the nature of material being manufactured. The apparatus here alluded to is called in Lancashire, Yorkshire, and other Northern Counties, a *reed*, but in many parts of England it is denominated a *slay*. Whence the latter term is derived it is not easy to conjecture, but the former no doubt owes its origin to the material formerly used, viz. bamboo or reed. In some Manufactures three or four threads of the warp are passed through between each two adjacent reeds; in others more or less; consequently, the closeness of reeds may be easily imagined in very fine stuffs, silks, muslins, &c.; and since the introduction of these fine Manufactures thin stripes of iron, steel, or brass have been substituted for the original reeds, but the name has been retained.

When this part of the weaver's loom was made of reed, and by hand, the process was as follows: a bamboo or reed was cut up into lengths between the joints, equal to the proposed breadth or depth of the reed. These were again split into thin pieces, and cut down between two fixed sharp knives or steel edges to their proper thickness, and rendered perfectly smooth. A piece of cane or wood a little exceeding the length of the reed was split up the middle, and also smoothed, and made of uniform thicknesses, and these were placed between supports something like the puppets of a lathe, at such a distance from each other as to admit the reeds, breadthwise, between them. Another cane was submitted to the same treatment, and placed below the first, and parallel to it, at a proper distance, according to the intended depth of the reed; and one of these puppets having an adjustment, these two double canes were brought to a considerable state of tension, and thus ren-

dered perfectly straight. The reeds were now introduced by hand between the open canes, a wax thread passed round each both at top and bottom, each one being driven as close to the preceding one as the thread would admit; and, lastly, any irregularity in the lengths of the reeds, which in this way projected a little above or below the bound cane, were cut down level with it by proper tools. It should also have been observed that two rather broad pieces of thin wood were introduced, one at the beginning and another at the finishing of the operation, to give to the reed when completed a certain degree of stiffness.

After finer works were introduced it was found difficult, if not impossible, to cut down reeds sufficiently thin, and this led to the introduction of steel and brass slips; but the operation was still performed by hand till very recently. A Machine is now employed for the purpose, which is extremely rapid in its performance, accurate in its operation, and altogether one of the most admirable pieces of mechanism it is possible to conceive.

The metal strips which form the reed are received in the form of wire properly annealed. This wire is placed between rollers, and flattened in one long strip of the proper breadth and thickness; it then passes through another Machine, to have its edges smoothed and dressed; in this state it is beautifully uniform, smooth, and bright. It is now placed on a reel near the reed Machine ready for use. The reed, as above described, when made by hand, was placed horizontally, but here the sides are placed vertically; the flattened wire is first introduced by hand, after which every thing else is performed by the Machine itself, which seizes the strip of metal, passes it between the open sides, and cuts it to its proper length; by another apparatus the thread, which lies between the reeds, performs a revolution, and is pressed to its proper bearing, when the Machine again brings the metal forward another length, cuts it off, the binding is again repeated and closed, and so on, with a rapidity and accuracy which no hands could possibly execute. The Machine we have seen is worked by steam power, but as great force is not requisite, at least in the actual construction of the reed, it might be worked by hand, or by any other means at the pleasure of the maker.

(457.) *Weighing Machines.*—Scales and weights, steel-yards and balances of all descriptions may be considered as properly falling under this head; it is not, however, intended to enter upon a description of these, but merely the larger sort of engines for weighing waggons and their loads, as hay, corn, coals, &c.

Some years back nearly every market town had its weighing house, something resembling a town gateway, so that a waggon might be driven in, the horses taken out, and the waggon with its load weighed; and then, the load being delivered, the waggon was again weighed and the difference was the weight of the hay, corn, or coals. The Machine commonly used in these weighing houses was a long and strong steel-yard in a room above the gateway or passage, a chain was passed under the waggon, and by a crane or crab the waggon was raised from the ground and then balanced as any smaller load may be with a less powerful apparatus. These weighing houses, however, have been long getting out of use, but the writer remembers one in a town in Norfolk forty years ago: it was removed about that time, and he does not recollect having seen one since. The Machine which succeeded to these weighing

Machinery.

Weighing Machines
Pl. xxxv.
Fig. 6, 7.

Manufactures.

houses are shallow recesses sunk in the ground and covered with a platform level with the surface of the road on which the waggon is driven, and weighed by an apparatus provided for the purpose. One of these Machines is represented, plate xxxv. fig. 6, where K L M N is a rectangular box, which has a platform lid or cover, of a size sufficient for placing on it the wheels of a cart or waggon. The box is about a foot deep, and is sunk into the ground till the platform cover is even with the surface. In the middle of the box is an iron lever supported on the fulcrum pin $i k$, formed like the nail of a balance, which rests with its edge on arches of hardened steel firmly fastened to the bottom of the box. The lever goes through one side of the box, and is furnished at its extremity with a hard steel pin $l m$, also formed to an edge below. In the very middle of the box it is crossed by a third nail of hardened steel $g h$, also formed to an edge, but on the upper side. These three edges are in one horizontal plane, as in a well-made balance.

In the four corners A A', E, E' of the box are firmly fixed four blocks of tempered steel, having their upper surfaces formed into spherical cavities, well polished and hard tempered. A B C D E represents the upper edge of an iron bar of considerable strength, which rests on the cavities of the steel blocks in A and C, by means of two hard steel studs projecting from its under edge, and formed into obtuse-angled points or cones. These points are in a straight line parallel to the side K N of the box. The middle part C of this crooked bar is faced with hard tempered steel below, and is there formed into an edge parallel to A E and K N, by which it rests on the upper edge of the steel pin $g h$, which is in the lever. In a line parallel to A E, and on the upper side of the crooked bar A C E, are fixed two studs or points of hardened steel B and D projecting upwards above half an inch. The platform cover has four short feet like a stool terminated by hard steel studs, which are shaped into spherical cavities and well polished. With these it rests on the four steel points B, B', D, D'. The bar A C E is kneed in such a manner vertically that the points A, B, D, E, and the edge C, are also in a horizontal plane. These particulars will be better understood by looking at the elevation in fig. 7. What has been said of the bar A C E must be understood as also said of the bar A' C' E'.

Draw through the centre of the box the line $a b c$ perpendicular to the line A E, B D. It is evident that the bar A C E is equivalent to a lever $a b c$, having the fulcrum or axis A E resting with its extremity c on the pin $h g$ and loaded at b . It is also evident that $a c$ is to $a b$ as the load on this lever to the pressure which it exerts on the pin $g h$, and that the same proportion subsists between the whole load on the platform and the pressure which it exerts on the pin $g h$. It will also appear, on an attentive consideration, that this proportion is nowise deranged in whatever manner the load is placed on the platform. If very unequally, the two ends of the pin $g h$ may be unequally pressed, and the lever wrenched and strained a little, but the total pressure is not changed.

If there be now placed a balance or steelyard at the side L K, in such a manner that one end of it may be directly above the pin $l m$ in the end of the lever E O F, they may be connected by a wire or slender rod, and a weight on the other arm of the balance or steelyard may be put in equilibrio with any load that can be laid on the platform. A small counterpoise being first hung on

to balance the apparatus when unloaded, any additional weight will measure the load really laid on the platform. If $a b$ be to $a c$ as 1 to 8, and E O is to E F also as 1 to 8, or if a common balance be used above, 64 pounds on the platform will be balanced by one pound in the scale, and every pound will be balanced by one-fourth of an ounce. This would be a very convenient proportion for most purposes, as it would enable us to use a common balance and common weights to complete the Machine; or it may be made with a balance of unequal arms, or with a steelyard.

Some have thought to improve this instrument by using edges like those of the nails of a balance instead of points; but unless made with uncommon accuracy, they will render the balance very dull. The small deviation of the two edges A and C, or of B and D, from perfect parallelism to K N, is equivalent to a broad surface equal to the whole deviation. We imagine that, with no extraordinary care, the Machine may be made to weigh within $\frac{1}{2000}$ th of the truth, which is exact enough for any purpose in commerce.

It is necessary that the points be attached to the bars. Some have put the points at A and E in the blocks of steel fastened to the bottom, because the cavity there lodged water or dirt, which soon destroyed the instrument with rust. But this occasions a change of proportion in the first lever by any shifting of the crooked bars: and this will frequently happen when the wheels of a loaded cart are pushed on the platform. The cavity in the steel stud should have a little rim round it, and it should be kept full of oil. In a nice Machine a quarter of an inch of quicksilver would effectually prevent all these inconveniences.

The simplest and most economical form of this Machine, is to have a balance or second steelyard; and to make the first steelyard E O F a lever of the first kind, viz. have the fulcrum between O and F, and allow it to project far beyond the box. The long or outward arm of this lever is then divided into a scale of weights, commencing at the side of the box. A counterpoise must be chosen, such as will, when at the beginning of the scale, balance the smallest load that will probably be examined. It will be convenient to carry on this scale by means of balance-weights hung on at the extremity of the lever, and to use but one movable weight. By this method the divisions of the scale will have always one value. The best arrangement is as follows: place the mark o at the beginning of the scale, and let it extend only to 100 if for pounds, or to 112 if for hundred weights, or to 10 if for stones; and let the balance-weights be numbered 1, 2, 3, &c. Let the lowest weight be marked on the beam: this is always to be added to the weight shown by the operation. Let the balance-weights stand at the end of the beam, and let the general counterpoise always hang at o . When the cart is put on the platform, the end of the beam tilts up. Hang on the heaviest balance-weight that is not sufficient to press it down: now complete the balance by sliding out the counterpoise. Suppose the constant load to be 312 pounds, that the counterpoise stands at 86 and that the other weight is 9; we have the load = $986 + 312 = 1298$ pounds.

The most simple weighing Machine for roads, is one recommended by the late ingenious Mr. Tredgold, but we are not aware it has been hitherto put in practice. This author from the numerous experiments he made on the elastic power of iron and steel, saw in their extreme

Machinery

Manufac-
tures.

uniformity of action, while the elasticity was not injured, the means of applying this property to the purposes of a weigh-bridge, whereby without any other apparatus the weight would be ascertained by the amount of deflection of the bar or bars supporting the platform. He has not pointed out any particular method of putting the idea into practice, but the means are so simple, that any person of common ingenuity could not fail of applying them in any case where such a Machine should be required, arranging the bearing points according to circumstances. Of late years weighing Machines of a smaller kind, as substitutes for common scales and weights for domestic and other purposes, have become exceedingly numerous. These, however, can scarcely be considered to belong to the present Treatise. Several of this kind are described under the article Balance, in our general alphabetical arrangement.

Mills.

Mills receive denomination, first, according to the power by which they are put in motion; and, secondly, according to the processes in which they are employed: according to the first classification we have hand-mills, tread-mills, horse-mills, and wind and water-mills, the general nature and construction of which have been already explained in section 80, *et seq.* It remains now to describe them according to the nature of the work they are intended to perform; but we shall confine our description to those simple processes only in which the object is crushing, grinding, or pulverizing; for although the denomination of Mill is given to several other Machines, yet we think it improperly applied. (See section 319.) The latter kind of Machines will, therefore, be given under the process or manufacture in which they occur in the second part of our Treatise.

Process of
barking.

(458.) *Bark-mill.*—Before attempting to describe this Machine, it may be well to offer a few remarks on the nature and qualities of bark, the process of barking, the drying and preparation it undergoes to render it in a proper state for being ground or torn by the mill. In the year 1604 an Act of Parliament was passed which prohibited the use of any but winter-hewn oak for the Royal Navy, which Act was repealed in 1808; and since that time it has been customary in this Country to fell the oaks, or at least to perform the operation of barking, in the month of May, as at that season the bark is more readily separated from the tree, in consequence of the rising of the sap; but the value of the timber is considered to be thereby deteriorated, and is by many persons supposed to be the cause of that disease in timber called the dry rot, which was so fatal during the war to the ships of the British Navy. Du Hamel, in his highly useful Work, *Sur l'Exploitation du Bois*, has some valuable remarks on this subject; see also Barlow's Essay on the strength of timber. Dr. Darwin, likewise, in his *Phytologia* remarks, that as the sap rises in all deciduous trees during the vernal months to expand their foliage, though, probably, in greater quantity in some trees than in others, it must consist not only of sugar and mucilage as in the maple and birch, but of various other ingredients in different trees, as appears from the taste of their young leaves, which has not been sufficiently attended to; and as some of these reside in the roots and in the sap wood, so others of them, perhaps, may reside in the bark, where they have been deposited during the preceding Summer, and become liquefied by the warmth of the Spring, or dis-

solved with the moisture, and conveyed upwards to the opening buds. Whence it is evident, he considers, that the bark of trees should be taken off for use in Winter or in the early part of the Spring before the buds begin to expand; as then a portion of these nutritious juices, of whatever nature they may be, is expanded on the young leaves, which generally possess the taste and qualities of the bark, although in a less degree. It may, nevertheless, be observed, that all these astringent or other qualities may reside in the alburnum of the trunk or roots of all perennial vegetables as well as in their barks; because the young leaves which pullulate on decorticated oaks have the same bitter flavour as the leaves of those which have not been decorticated, which may in part be derived from the bark of the root that is still in the ground, and be carried up the vessels of the sap wood to the new buds. Hence the bark of oak trees should be taken off during the Winter; but when the sap juice residing or ascending in the vessels of the alburnum becomes more liquefied by the warmth of the Spring, or is mixed with moisture, and pushed up with great force by the absorbent vessels of the roots, it oozes out in some degree between the alburnum and the bark, and thus the bark becomes much more easily separated from the tree; whence this business, as has been already observed, is done more readily in the Spring. As at this time the process of germination of the buds commences, which extracts in some measure the virtue of the bark, it is advisable that the peeling should take place immediately this facility appears, whether the tree be cut down or not, as the process of germination continues on new-felled trees while they lie on the ground.

The tool commonly made use of for this purpose is either made of bone or iron. If of the former, the thigh or shin-bone of an ass is preferred, which is formed into a two-handed instrument by a handle of wood fixed at the end, when used for the stem or larger boughs. This edge, once given by the grinding-stone, keeps itself sharp by the wear which afterwards takes place in the operation.

The method of drying bark is generally by setting it in a leaning posture against poles lying horizontally on forked stakes; but in wet seasons, or when the ground is naturally moist, it is laid across a line of top-wood, which raises the bark about a foot from the ground. By this practice no part of the bark is suffered to touch the earth, and it is, perhaps, upon the whole the best method in all seasons and situations. When sufficiently dried it is laid up in houses, or piled in stacks, to be sold to the tanner.

The quantity of bark consumed in the manufacture of leather in England amounted, in 1821, to 117,040 tons, of which 90,000 were imported; the remaining 27,000, which is less than a quarter of the whole consumption, being all that were contributed by England.

Having offered these few remarks relative to the bark itself, we may proceed to describe the bark-mill which is used by tanners for the purpose of tearing or grinding the bark into small portions, in order that the tanning property, or *tannin*, may be more readily extracted from it. Various methods are employed for this purpose. Horizontal and vertical stones are sometimes used; in others, the bark is simply passed between two rollers, which have grooves in their circumferences; in which case the bark is not ground to powder but merely bruised.

(459.) A patent was granted to Mr. James Weldon of

Machinery.

Manufactures.

Weldon's bark-mill. Pl. xxxvi. Fig. 1.

Lichfield, in 1797, for a mill for grinding bark, which is still very commonly adopted. Pl. xxxvi. fig. 1, is an elevation of this mill. A and B are pieces of timber connected with the sides of the mill house which support the Machinery. E is a cast iron shaft, which has a bearing at its upper end in a plumber block attached by bolts and nuts to the beam A. The shaft C has a bevelled wheel E E at the upper part, which engages in a similar one on the horizontal shaft F, by which motion is conveyed to the mill. This shaft may be put in motion by a steam engine, a horse or water-mill, or any kind of mover. When conveniently situated, tanners sometimes employ a wind-mill for the purpose, which is of course less expensive; but it is not so certain of producing a regular supply, and is not therefore very frequently adopted. G is a cylindrical body forming the internal part of the mill which is firmly attached to the vertical shaft C; it is made either of wrought or cast iron, and upon its surface, which is the inner grinding surface of the mill, are formed two rows of teeth, of which the upper ones H H serve to break the bark, and the lower ones K K, which are smaller and more numerous, to grind it. The lower part of the vertical shaft, which projects beyond the conical part G, works in a movable brass step L, in order that it may be raised or depressed, according to the nature of the substance to be ground, or to the degree of fineness required. This brass step slides in a groove or mortise in the cross bar R of the lower framework, and is very accurately fitted, in order that it may have no lateral motion. M is a screw which works in a nut let into the cross beam T, and is turned round by a handle H, so that by this means the step is readily raised or lowered when required.

S S is a circular piece of cast iron, the lower part of which is made conical, and is firmly attached to the uprights Q Q by bolts and nuts. Upon its inner surface are formed teeth, which are similar to and work against those on the piece C, and perform with them the grinding process. These teeth are made at an angle with the vertical axis, and meet the inner teeth, which are made at a similar angle, but the reverse way, after the manner of a pair of scissors, by that means cutting and tearing the bark to pieces, which, when reduced into sufficiently small particles, falls through into a wire sifter which separates the finer and coarser parts of the powder to any degree that may be required.

Chapman's bark-mill. Fig. 2.

(460.) Fig. 2 is a representation of a mill for tearing and crushing bark, invented by Mr. Chapman of Yorkshire, in which the process is performed by horizontal rollers. The view shown in the plate is an elevation of the mill, with the front side of the framing removed, (in order to show the interior construction.) • Motion is communicated to the mill by a spur wheel attached to the horizontal shaft B. Upon the same shaft is a barrel or roller C, termed the rag barrel, which has twenty rows of plates or more on its circumference, according to the power required; these plates are laid to overlap each other, in order that they may form cutting edges. D is a smaller roller, the circumference of which is formed in a similar manner, but with the cutting edges turned in the contrary direction: this roller is put in motion from the spur wheel by two pinions, in order that it may be turned in an opposite direction and at a greater velocity. by this means the cutting edges of the rollers meet, and the bark being placed between them is of course torn and cut to pieces: d is a screw which serves to adjust the distance of the rollers; it has a bearing in the upper

part of the framing, and in a lug or projecting piece cast upon the lower plate of the plumber block in which the axle of the roller D revolves, and thus when turned round it causes a lateral motion to be given to the roller C.

The bark after passing these rollers falls upon the grinding plate D where it is further reduced. This plate is attached to a framing of cast iron which rests upon the cross bars E E, and may be adjusted in both a vertical and horizontal direction, by means of screws in the sides of the framing and in the part upon which it bears; by this means the rollers may be set so as to grind the bark to any degree of fineness that may be required. As the rag barrel is liable to become at times clogged with bark, a wheel G, with spikes on its surface, is made to revolve just clear of the circumference, which gathers the bark and keeps the barrel clean.

H is a spout which receives the bark when ground, and conveys it to the basket k; it is afterwards passed through a cylinder composed of wires of different degrees of fineness, which is put in motion by any means from the main shaft. The dust as it passes down the cylinder falls through into two bins, the upper one to receive the fine dust, and the lower one the coarser dust usually termed *hand dust*. A considerable quantity of a very coarse description, which cannot pass through the wires, falls out at the lower end of the cylinder: this is generally passed again through the mill to be further reduced.

(461.) Mr. Bagnall, of Worsley in Lancashire, took out a patent for a bark-mill, in which the process of grinding was performed by horizontal millstones. The bark was first placed upon a grating, where it was chopped into small pieces by knives attached to long levers; these levers were suspended upon pivots at about a quarter of their length, and were raised by ropes at their extremities, so that when relieved they fell with considerable force upon the grating, and in this way reduced the bark until sufficiently small to pass through the grating, when it was received in a trough which conducted it to the millstones.

The powder which came from the stones was caught in an inclined riddle or sieve, through which the fine dust escaped, while the coarser portions passed down and were received in a trough, where they underwent a further process of being beaten and bruised by a hammer to render them fit for the tanner.

This mill did not, however, possess the advantages expected by the patentee; the millstones are liable to be clogged from the fibrous nature of the bark, and it has, in consequence, not been much adopted. It was provided with an apparatus for scraping off the hair and extraneous matter from the hides, technically termed *beaming*, which very commonly forms a part of bark mills. The hides are placed upon a kind of wooden carriage, which is rendered easily movable upon a tram road, and a knife attached to a beam above, having a reciprocating motion from the Machinery, passes along the surface and rubs off the hair. The sliding rod or beam to which the knife is fixed is usually inclined about ten degrees from the horizon; it receives its motion at the upper end from the Machinery by means of a crank, and the other end rests upon a suspended roller, which may be raised so as at any time to bring the knife clear of the hide. When the beam arrives at the bottom of the stroke it engages a lever having an arch head, which turns upon a pivot at its lower extremity, and which

Machinery.

Bagnall's bark-mill.

Manufac-
tures.

returns with the beam and raises it clear of the hide, so that the operation of scraping is performed in the descending stroke only. When the beam arrives at the top of the stroke, the lever disengages itself and falls back into its original position to be again taken up by the next stroke. The scraping knife is usually attached to a string, which allows it to yield to any irregularities in the surface of the skin, and prevents damage to the hides, which otherwise is liable to occur. The hides are readily shifted by the carriage when sufficiently scraped, and a new portion of the surface is prepared for the action of the knife during the return of the beam.

Scouring of tanned leather for the use of the currier may be done by the same Machine simply by removing the knife and fixing a stone with a push, either before or after it, in its place. For more on this subject, see the article Tanning.

Quantities
of bark im-
ported and
exported.

(462.) *An Account of the Quantities of Bark for Tanning imported into and exported from the United Kingdom, and cleared for Consumption, together with the Rates of Duty and Net Amount of Revenue in each Year, from 1820 to 1831, both inclusive.*

Years.	Importations.	Exportations.	Consumption.	Rates of duty per cwt.	Net Revenue.
	Cwts.	Cwts.	Cwts.	s. d.	£.
1820	319,342	..	316,790	0 8	10,742

1829	1,013,684	1,143	1,007,938	..	36,619
1830	1,007,928	1,390	997,665	..	35,222
1831	970,523	2	964,379	..	32,727

An additional duty of one-fifth on the existing rates of duty has been levied on bark in common with other goods imported in ships belonging to the Kingdom of the Netherlands, under Order in Council 30th January, 1826.

Cement-mill.

Cement-
mills.

Cement-mills are employed to reduce certain stones or concretions of clay containing veins of calcareous matter into the state of powder in order to form cements. The same description of mills are also employed to grind puzzolana, a volcanic mineral exported from Italy, which, when added to mortar, gives it the property of setting under water.

Parker's
cement.

(463.) *Parker's cement.*—The principal cement of English production, is thus denominated from the name of the inventor, Mr. James Parker, of Northfleet in Kent, who took out a patent for this important invention in the year 1796. It is sometimes also called Roman cement. The patent consisted in employing certain mineral productions in the formation of a cement, which should be much stronger and harder than any at that time prepared by artificial means, and which also possessed the property of setting either in or out of water in ten or twenty minutes after being mixed. The stones previously to being ground are broken into small fragments about

the size of a walnut by hammers, and then burned in a kiln or furnace with a heat nearly sufficient to vitrify them. The stones are of so soft a nature that the operation of breaking is usually performed by women or children, who by the aid of a small hammer can readily reduce them to the required size. When burned, they assume a red appearance and are a little further softened; they are then prepared for the process of grinding.

(464.) *Puteolean powder*, now denominated *puzzolana*, is a light porous friable mineral of a red colour: it was discovered by the Romans at the town of Puteoli, from which it takes its name. It is generally supposed to derive its origin from the concreted volcanic ashes thrown out from Vesuvius, near to which mountain the town of Puteoli is situated, and seems to consist of a ferruginous clay calcined by the action of the volcano. When mixed with common mortar, it not only acquires a remarkable hardness in the air, but becomes as firm as stone even under water.

Puzzolana was first brought into this Country at the time Westminster bridge was building, by a merchant at Plymouth, who expected to dispose of it to advantage for that work. He, however, failed in his speculation, as neither the Commissioners nor Engineers would make a trial of it; and it remained by him undisposed of until Mr. Smeaton tried its efficacy as a cement for the Eddystone lighthouse, and found it to answer so well that he purchased the whole of it. Since that time, it has been exported in considerable quantities from Civita Vecchia in Italy, and is now very generally used in all under-water constructions. It arrives in this Country in lumps, which require some preparation previously to being passed through the mill; Mr. Smeaton recommends the following: *viz.* to sift it through two wire sieves, the finer of which should have about seven or eight meshes per inch running. The dust which passes through the fine sieve is fit for use, the remainder must be further reduced in the mill. It is advisable that the larger portions left in the first or coarse sieve should be broken and examined in order to pick out a kind of grey stony matter, as well as other heterogeneous substances that get accidentally mixed with it, which will readily be distinguished from true puzzolana. This grey stone has no cementing quality; it is also difficult to grind.

The part to be ground must then be made perfectly dry either by the sun or by a drying kiln, otherwise it is apt to clog the stones.

(465.) Fig. 1, pl. xxxvii. is a side elevation of a mill erected in his Majesty's Dock-yard at Sheerness for the purpose of grinding cement, worked by a twelve-horse power steam engine. A A A are the walls of the engine house and mill, R R R the roof, and B B the main shaft of the engine from which motion is given to the different parts of the Machinery.

The cement previously to being ground is passed between two iron rollers, one of which is seen at C in the figure; this roller is put in motion when required by means of a clutch *p p*, from a spur wheel on the main shaft, which engages the wheel E E and communicates its motion by the spur wheel F F to a similar one on the shaft of the other roller, so that the rollers meet each other moving at the same velocity. The lumps of cement are placed in a hopper *h' h' h'*, and are conducted by a trough *t t* to pass between the rollers, in which process they are reduced into small fragments.

Cement-
mill at
Sheerness
described.
Pl. xxxvii.
Fig. 1.

Manufac-
tures.

The cement is caught in a sack as it comes from the rollers, and is conveyed to the upper floor of the mill, by aid of Machinery, termed sack tackle; this consists of a pulley *a a*, which may be put in motion by a similar one *b b* on the main shaft when required by a lever, (not seen in the figure,) which tightens the rope *r r* and thereby causes sufficient friction to carry round the upper pulley, so that in the ordinary state of the mill the lower pulley alone revolves. A rope, to which the sack is attached, passes round a drum on the spindle of the upper pulley, and is consequently taken up with the sack when the Machinery is put in gear.

The grinding is performed by two horizontal millstones which are inclosed in a wooden case *G G* to prevent the escape of the dust; the lower one is stationary and well bedded upon the beams *e e*, and the upper one is attached to a spindle which is put in motion by the Machinery. The mill represented in the drawing contains two pair of stones, one being placed on each side of the cog wheel *H H*. This cog wheel puts the upper stone of each pair in motion by a spur wheel which is attached to a vertical spindle passing through a hole in the lower stone, and receives its motion from the main shaft by a bevelled wheel *m m*, which engages a similar one *n n* on the lower end of the vertical shaft *h h*. The millstones have grooves or channels on the face of them cut obliquely from the circumferences to about an inch or an inch and a half on one side of the centre, but in the reverse direction in the upper and lower stone, so that when in motion the edges are continually meeting each other, and by that means crush and break the cement, which when reduced to powder passes along them to the circumference whence it escapes into a trough. The stones make about a hundred and fifty revolutions in a minute; they are very commonly made of stone from the Peak of Derbyshire. French burrs, however, answer the purpose best, particularly if it is required to grind puzzolana; for though it may be done by other kind of stones, yet as it is mixed with flinty matter which cannot be all picked out, no other stones will stand the service for any length of time. The construction and manner of cutting the grooves is exactly similar to that of corn-mills, to which article we beg to refer the reader who is desirous of more particulars on this subject.

The cement when it arrives at the upper floor from the rollers is emptied into a large hopper *K*, from which it proceeds by a spout to a smaller one *L*, and thence into a trough *M* which conveys it to a hole in the upper stone. The trough is inclined, and is kept in continual motion by a small iron cross *g*, which revolves with the upper stone and keeps tapping it so as to cause a regular supply to pass down to the stones according to their velocity. The cement when ground passes out at the circumference of the stones into the spout *k* as above described, which conveys it to two sieves, (one of which is seen at *ll*,) in order to separate the fine dust from any hard lumps which may have been imperfectly ground. The sieves receive a rapid reciprocating motion from the Machinery by a rod attached to them and to a small crank *r* upon the vertical spindle *p p*, which receives motion from the cog wheel *H H* by a small spur wheel or pinion fixed upon it. This serves more effectually to separate the fine dust which passes through into sacks for use.

(466.) *Mortar-mill*.—The part marked fig. 2 in the drawing, is a mill for the purpose of grinding calcined

limestone or chalk into powder in order to form quick or hot lime. This is very commonly termed a *mortar-mill*. The lime in this state is preferable to slacked lime in the formation of cements for many situations in building, as it causes them to set quicker. The proper application of these different states of lime will be better treated of when we speak of the composition of cements in a subsequent part of this article. At present we shall confine our remarks to the mechanism of the mill.

A A is a vertical shaft or spindle which has a bearing at its upper end in a plumber block attached to the cross framing, and at the lower end in a brass step which is let into the cast iron plate *B B*. To this is fixed at right angles a horizontal shaft *c* upon which the mill stones *D D* revolve, consequently when the shaft is put in rotation from the engine by the bevelled gear *a a b b*, these stones have two motions, one on their axles and the other round the vertical shaft *A A*. The lime to be ground is placed on the cast iron plate *B B*, which is very firmly bedded upon timbers, and the stones pass over it grinding and crushing it into a small powder. The stones are commonly fixed at different distances from the vertical shaft so as to describe two different tracks on the cast iron plate. Curved pieces of iron termed rakes are attached to the shaft and revolve just clear of the surface of the plate; these serve to collect the lime in the track of each roller in order that it may pass over it. This description of mill is sometimes used for grinding Parker's or Roman cement. The horizontal stones are, however, very much preferred, as they produce a finer powder which is essential to its property of setting quickly.

There are in addition to the above other mills used in the formation of cements for the purpose of mixing the ingredients well together, commonly called *Pug-mills*. The common method of mixing lime and sand by the shovel is very imperfect, and to this may be attributed the badness of the mortar of our common edifices.

(467.) *Pug-mills* are of such simple construction, and are so varied according to circumstances, that it would be useless to describe them; a few general remarks, therefore, are all that seems necessary to be given on this head.

The most complete form of this mill is that which was generally made use of by Smeaton, viz. the running stones, which do not differ from the one above described for grinding quicklime, except that it was put in motion by a horse which walked round at the extremity of a long lever attached to the vertical shaft.

In the common pug-mill, a circular trough is made in the ground, with a post firmly fixed in the middle, a long lever is attached to it so as to be movable, at the end of which a horse walks round. The lime and sand are thrown into the trough, and are mixed up by a kind of rake which is attached to the lever.

Pug mills consist sometimes simply of a barrel fixed firmly in the ground, having a vertical spindle with spokes or projecting pieces attached to it, turned round in it, which mixes up the mortar. In fact, their operation is so simple that the ingenuity of the builder will always devise a means of effecting his purpose according to the situation and circumstances in which he is placed.

Composition of Cements.

(468.) Before entering into a description of the various cements employed in the construction of buildings, it is

Machinery
Mortar-
mill.
Fig. 2.

Pug-mill

Manufac-
tures.

Of lime.

desirable to make a few remarks on the nature and properties of lime, a mineral which composes a greater or less proportion of almost every cement, and seems indeed essential to their cementing property.

(469.) *Of lime.*—This substance is usually found combined with carbonic acid in the form of chalk, marble, limestone, and sea shells, from which the carbonic acid is driven off by the process of burning them in kilns.

There are two modes in which lime acts as a cement: in its combination with water, and in its combination with carbonic acid. When quicklime, which is the produce of the kiln after burning the limestone, is made rapidly into a paste with water, it soon loses its softness, and the water and the lime form together a solid coherent mass termed hydrate of lime, which is composed of about one part of water to three parts of lime.

When quicklime is taken fresh from the kiln, and a due quantity of water thrown on it, it splits with noise, swells, gives out a burning slightly caustic vapour, and falls into a thick creamy mass. This operation is termed slacking. When lime is slacked and mixed with sand as in common mortars, it first solidifies as a hydrate, and is then slowly converted into carbonate of lime from the atmosphere. Mr. Tenant found that mortar of this kind had in three years and a quarter regained sixty-three per cent. of the quantity of carbonic acid, which constitutes the definite proportion in carbonate of lime. The hardness of the mortar in very old buildings depends upon the perfect conversion of all its parts into carbonate of lime. The purest limestones are best adapted for making this kind of mortar: the magnesian limestones make excellent water cements, but act with too little energy upon carbonic acid to make good common mortar.

The Romans, according to Pliny, made their best mortar a year before it was used, so that it was partially combined with carbonic acid before it was employed.

Burning
lime.

In burning lime, there are some particular precautions required for the different kinds of limestones. In general, one bushel of coal is sufficient to make four or five bushels of lime. The magnesian limestone requires less fuel than the common limestone. In all cases in which a limestone containing much aluminous or silicious earth is burned, great care should be taken to prevent the fire from becoming too intense; for such lime easily vitrifies in consequence of its affinity for silica and alumina. And as in some places there are no other limestones than such as contain other earths, it is important to attend to this circumstance. A moderately good lime may be made at a low red heat, but it will melt into glass at a white heat. In limekilns for burning such lime, there should always be a damper.

Mr. James Frost of Finchley, in the County of Middlesex, took out a patent for an improved process of calcining calcareous and other substances, which consisted in employing retorts or furnaces which excluded the atmospheric air, and in removing the substance when sufficiently burned into vessels to cool, which were also air tight.

This is certainly a considerable improvement upon the common method employed in limekilns, as a considerable quantity of carbonic acid is absorbed during the cooling.

In general, when limestones are not magnesian, their purity will be indicated by their loss of weight in burning: the more they lose the greater is the quantity of

calcareous matter they contain. The magnesian limestones contain more carbonic acid than the common limestones, and all of them lose more than half their weight by calcination.

The different kinds of lime used in the composition of mortars and cements for buildings, are commonly distinguished by the terms *fat* and *lean* lime; the former, when quick and reduced to powder, absorbing so much water in slacking as to triple its bulk; the latter increasing only its own bulk or one and a fifth; but between these extremes there are so many intermediate qualities of limestones, as to render it difficult to draw a line of distinction between them. This denomination of lean lime has been since applied exclusively to all those species which have the property of hardening or setting under water.

(470.) M. Vicat, engineer in the *Corps Royal des Ponts et Chaussées* of France, made a set of very interesting experiments on lime, mortar, and water cements, which were published by the desire of that Corps, and also of the Institute of France. He gives the name of *hydraulic limes* to those which, when properly burned, have the property of hardening in a short time under water, and of *common limes*, those which have not that quality; *fat limes*, those which when calcined and plunged under water absorb in slacking from 260 to 360 per cent. of their weight of water; *middling limes*, those which absorb from 230 to 260; and *lean limes*, those which take up from 100 to 230.

The hydraulic limes are sometimes white or scarcely coloured, but generally they are grey or *clay* coloured. When they are slacked to the consistence of a thin cream and then plunged into water, in setting they part with a portion of the water with which they are combined. On the other hand, when slacked only to the thickness of a stiff paste and then immersed in water, they absorb an additional portion of this fluid in setting. There is, therefore, a determinate quantity which this kind of lime requires for setting, and this process takes place independently of exposure to air or external circumstances.

Common limes slacked under water take up much more water than they can solidify, and as they have not the power of rejecting what is superfluous, they remain constantly in the state of soft paste, not only under water, but in the pits in which they are slacked, when covered with sand or earth.

There are some limes which have an intermediate quality between the two above mentioned, which acquire some consistence after slacking but without ever setting properly.

The qualities of lime not only vary in different districts, but even in different parts of the same quarry; which will sometimes yield every variety of lime from the most completely hydraulic to that which remains perfectly soft after slacking.

Bergmann, and after him Guyton, have attributed the water-setting property to a small proportion of manganese; Saussure to silex and alumine; Descotils, from the analysis of the limestone of Senorches, to a large proportion of silicious matter disseminated through it in fine grains, and which appears to amount to a fourth of its weight. But, on the other hand, the limestone of Metz, so eminent for its hydraulic qualities, contains only 5 or 6 per cent. of silex; and M. Vicat has ascertained by numerous assays, that iron and manganese are not indispensable to this quality. As there is yet

Manufactures.

much uncertainty on this subject he remarks, "that as in large works it is of the utmost importance to be assured of the quality of the lime employed, it would be better always to make a previous assay of the limestone." For this purpose it may be calcined in a limekiln, or otherwise in a forge furnace fed with charcoal; and when sufficiently burned it may be slacked with water to the consistency of thin paste, and covered with water in any convenient vessel. If at the end of a week or a fortnight the mass of slacked lime has stiffened so as to resist the impression of the finger, it is a proof of its hydraulic quality, but if it remains soft it is only common lime.

The hydraulic limes are useful not only as the bases of water cements, but form excellent mortar for buildings exposed to the air, when mixed up with common sand. It is true that masons prefer the fattest lime for common purposes, but this is easily accounted for, from the much larger proportion of sand they will take up, which is the least expensive ingredient; but it is surprising that Architects have examined the hydraulic limes only in respect to their water-setting qualities, and not as to their use in works exposed to the air.

Vicat's experiments on different modes of slacking.

(471.) M. Vicat's first experiments were made with a view of trying the effects of different methods of slacking lime. The first was the common method, as has been before described. In the second, the quicklime was plunged into water for a few seconds and then withdrawn; it soon began to hiss, split with noise, and fall into powder. This is called powder of lime by immersion; it may be preserved for a long time in this state provided it is kept dry, and does not heat when afterwards slacked by water. We owe this method of slacking to M. de Lafaye, who published it in 1777, as a secret discovered from the Romans.

The third method consists in exposing the quicklime to the gradual action of the atmosphere until it falls into powder. There is a slight evolution of heat during this process, but without visible vapours.

The following is the quantity of water absorbed and the volume of liquid of equally pasty consistence, or cream of lime, produced by the three above-mentioned modes of slacking.

	Weight of water absorbed.	Volume of cream of lime.
100 parts by weight of common fat lime slacked by the first process.	236	310
ditto by the second	131	104
ditto by the third	148	176
100 parts lean coloured hydraulic lime slacked by the first process.	105	137
ditto by the second	71	127
ditto by the third	68	100
100 parts of lean white hydraulic lime slacked by the first process.	110	130
ditto by the second	80	117
ditto by the third	70	108

Upon these results it may be observed that equal quantities of the same lime will give pasty liquids of the same consistence, but with different portions of water, accordingly as one or other mode of slacking is adopted. This, M. Vicat remarks, evidently depends on the degree of continuity which the particles of lime contract by evaporation. The swelling, and superior quantity of water absorbed in the first process, shows that it is in this in which the division of its particles is carried to the highest degree. In confirmation, it may be added, that

VOL. VII.

in all but the perfectly white limes, the colour after Machinery. slacking is deeper by the second and third processes than by the first, resembling, in this respect, vermilion and other coloured substances, whose tint of colour is brightened in proportion as they are more minutely divided. It therefore follows, that in order to compose a mortar made with lime slacked by immersion in water, or by spontaneous exposure to the air, in which the consistence is required to be in appearance the same, as fast and binding as when lime is slacked in the ordinary way, a greater proportion of lime to the other ingredients of the mortar must be employed in the former than in the latter case.

(472.) *On the combination of water with lime.*—When pure lime, slacked to the consistence of cream, is dried in a crucible, it gives a compound termed hydrate of lime. This is white, pulverulent, and attracts the carbonic acid of the atmosphere.

Many trials have shown that the quantity of water employed in the slacking has a great influence on the hardness of the hydrate produced by the evaporation of the superfluous water.

M. Vicat made the following experiments on the quantity of water requisite to give the greatest degree of hardness to the hydrate of lime.

Description of lime.	Parts by weight experimented on.	Parts of water used to slack it.	Number expressing the relative hardness.
Common fat lime . .	100	137	0.126
	100	183	0.222
	100	315	0.068
Hydraulic lime . . .	100	70	0.014
	100	92	0.051
	100	246	0.010

From these experiments it appears that 183 with the first specimen, and 92 with the second, gave the best result.

(473.) In pursuance of these inquiries, M. Vicat tried the relative resistances or tenacity of quadrangular prisms formed of different species of lime, slacked according to the three methods already mentioned; they were of an indeterminate length, but had for their section a rectangle of 1.57 inch base and 0.98 inch height. He exposed them for several days to the rays of a Summer sun, and thus obtained dry hydrates covered with a very thin crust of revived carbonate of lime, which readily scaled off. The breaking force was applied, by fixing the prism horizontally on a block, fastening it by an iron slip, and hanging over the projecting edge an iron spur, supporting a box, the weight of which was gradually increased by a small shower of fine sand until the prism broke.

These experiments gave results of which the following is an abstract.

Description of lime.	Method of slacking.	Number expressing the relative tenacity.	Number expressing the relative hardness.
Common fat limes	1st method	2490	0.1696
	2d ditto	450	0.0713
	3d ditto	1707	0.0850
Hydraulic lime . .	1st method	864	0.0488
	2d ditto	392	0.0446
	3d ditto	245	0.0358

2 z

Manufac-
tures.

From these experiments it appears that with the common fat limes the greatest tenacity was given by the first or common method of slacking; the next, by the third method, spontaneous evaporation; and the last by the second method, which is that of immersion.

That with hydraulic limes the tenacity is greatest with the first method, next in degree with the second, and least with the third.

It is not within our limits to give all the observations and remarks made by M. Vicat during these investigations; we shall add those only with which he concludes this section of his paper.

Deductions
from Vicat's
experi-
ments.

(474.) First. That very fat white limes may form, by the assistance of water alone, bodies as hard as a multitude of natural limestones, particularly when the common mode of slacking is used, and when a firm binding consistence is given to the paste, and nothing opposes its shrinkage on drying.

Secondly. That the action of the air and length of time increases the hardness of the slacking limes exposed to it.

Thirdly. That the hydraulic limes, particularly those which are coloured, give by the action of water only light and soft compounds.

Fourthly. That the action of the air increases their hardness, but not in any degree equal to that which it gives to the hydrates of the fat limes.

Fifthly. That the resistances of these different compounds are not at all proportional to their degrees of hardness.

If it were possible to make moderately large blocks or tables of mere lime and water, the increase of hardness produced by exposure to the air could not be reckoned as any thing, for ten years would not regenerate one-twentieth of an inch in depth. We must, therefore, only take into account the firmness of texture produced by the lime and water alone; and this varies, in the most favourable circumstances, from 2.745 to 3.690, good brick being 5.690.

But the chief difficulty that would arise from the use of hydrate of lime is the great shrinking that takes place as it dries. When prisms are made of it, that do not exceed the dimensions of a very small brick, and are set to dry on a floor, to which they do not adhere, they shrink without cracking, and dry into solid masses, covered, however, with a slight efflorescence which rounds off the angles and corners. But if it were attempted to fill moulds with this material it would dry irregularly, and cleave to the moulds, and would turn out full of cracks and unfit for use. No advantage is got by kneading it before moulding.

The fat limes shrink the most; and more in proportion as they have been more thoroughly divided in slacking. This shrinking will always oppose the use of mere lime as a mortar, unless in works under water, or in thin coatings of stucco, previously made fit for use by long and laborious kneading. Vitruvius, indeed, speaks of light works of the Roman masons made of lime alone, and called by them *albaria opera*: and it is the custom in the East Indies to coat the walls with a fine stucco, made of quicklime, beat up with milk, oil, and other ingredients. It would not be difficult to make thin slabs of mere hydrate of lime, which, when well smoothed and polished on sandstone, would imitate fine white marble, and might be employed in mosaic work.

Water has no action on the hydrates of the hydraulic limes; but it dissolves and decomposes the fat limes.

To show the action of water on the latter, let some balls be made of a slacked fat lime and water, and when dry expose them to the air. In a month or two they will be covered with a hard crust of regenerated carbonate of lime, and will be insipid when the tongue is applied to the surface; but when broken in two, the inner portion will show the causticity of the lime by the well-known acrid taste. If the broken portions are then immersed in a current of water all the inner part will be dissolved out, leaving only the exterior shell of carbonate of lime. Descotils, reasoning from the fact, that during the burning of limestone the silex which may be united with it undergoes such a change as to be rendered soluble in acids, concludes that this substance contracts an intimate union with the lime, and thus makes it less easily acted on by the atmosphere or by water. This observation will very well explain the resistance which the hydrates of hydraulic lime oppose to the dissolving action of water; but it appears not so easily reconcilable to the very weak consistence which they acquire by exposure to the atmosphere.

We add here a Table containing the properties of nine different water limestones analyzed by Smeaton during his experiments to ascertain a proper cement to be employed in the erection of Eddystone Lighthouse.

(475.) On cements exposed to the action of the air, usually termed mortars.—These are composed of a mixture of lime and sand; they are subjected to a number of vicissitudes to which water cements are not liable; they are sometimes in contact with earths of different chemical qualities, exposed at time to the changes of rain, sunshine, frost, and thaw, are seldom in a permanent state of dryness, except in the interior of buildings; whereas water cements have only to contend with one element which undergoes but slight variations of temperature. It is, therefore, to be regretted that the former have not been more attended to by scientific men.

The solidification of common mortar proceeds, according to the hypothesis of Dr. Ure, from the re-formation of the hydrate of lime into the carbonate of lime by its attraction of carbonic acid from the atmosphere. This hypothesis is, however, objected to by M. Vicat; who, although he allows that there is a remarkable affinity of hydrate of lime for carbonic acid, considers that this effect cannot reach far, and can never penetrate into the centre of thick walls, or the mortar of foundation work. It may, however, be observed that the mortar in the interior of thick walls is known to require a very great

On mortars.

Hypotheses
as to the
cause of
hardening.

Manufac-
tures.

length of time before it becomes indurated, and is generally inferior in hardness to that nearer the surface. A fact related by Mr. Smeaton may serve to illustrate this point. Having had occasion to take up a large flat stone of a close grain, which had probably lain above a century at the bottom of a malt cistern, he found that it had been well bedded in mortar, which had become coagulated to the consistence of cheese; but it had so far retained its natural humidity that he was enabled to beat it up to mortar without any addition of water, and afterwards having exposed it to the air, it set to a stony hardness, and appeared as good mortar as any which that part of the country produced.

Several other hypotheses have been given to explain the solidification of common mortars. M. Faujas St. Fond thus expresses himself on this subject: "The water which holds the particles of lime in maceration for a length of time takes possession of the whole of the fixed air (carbonic acid) which is concentrated within it; it then acquires the power of reducing and binding the absorbent earth when wrought up with it, and uniting it to quartz. And as the evaporation of the liquid takes place in a slow and insensible manner, or rather as one portion of the liquid combines with the materials to make water of crystallization, this operation becomes more perfect in proportion as it is longer and more thoroughly elaborated."

This explanation supposes a crystallization, the existence of which it is difficult to prove: when the lime is examined in the fracture of a portion of good mortar, taken up from the foundation of an edifice, shining particles appear which seem to indicate a confused crystallization; but some days of exposure to the air are sufficient to disperse this appearance, and to make the whole return to the common dead white of slacked lime; this deception, therefore, depends on a very small quantity of uncombined water which disappears by spontaneous evaporation. It is well known that if water saturated by carbonic acid is poured into lime water, the mixture first grows turbid, but clears again by a further addition of carbonic acid, which redissolves the precipitated carbonate of lime, and this again falls down by ebullition or slow evaporation. But how is it possible to conceive a similar effect on mortar, the consistence of which is pasty, and which retains no more carbonic acid than the last portions which the fire has not been able to expel from the lime in burning? whereas for this explanation of M. Faujas to be true, it would require the presence of an excess of carbonic acid even more than the raw limestone contained before burning.

A variety of other opinions have been formed by different authors on this subject. Lorient, the inventor of the celebrated Lorient Cement, considered the lime as a simple gauge or matrix, and the sand merely in the light of a foreign body which only increases the bulk of the mixture; but if this were really the case, and if the lime had no chemical action on the silicious grains which it incloses, it is obvious that it would set under water as readily without as with the sand which the mortar contains.

(476.) *On the properties of sand.*—Builders do not agree on the comparative qualities of fossil sand, river sand, and sea sand. Mr. Rondelet is, after Vitruvius, the author to whom we owe the greatest number of particulars on this subject; and he concludes that we cannot form an exact opinion of the goodness of sand from the place whence it is taken, but only from

the colour and the quality of the substances of which it is composed; and he gives a preference in sand of the same species to those samples which have the darkest colour, excepting, however, the yellow.

M. Vicat made, in pursuance of his inquiries on cements, a set of experiments to ascertain the relative resistance presented at the end of a year by different mortars, in which he used the sand of the Dordogne, where the quartz predominates, and which also contains mica, felspar, schorl, and basalt.

The extent of these experiments will not permit us to give them at full length; we shall therefore simply give the remarkable conclusions which he came to from their results.

First. That the samples of lime which when merely wetted without other addition form the most solid bodies, are those which produce the weakest mortars with sand.

Secondly. That quartzose sand does not contribute, as has been generally supposed, to increase the cohesion of every species of lime indiscriminately; but that it is useful to some, prejudicial to others, and has no sensible effect on a third class.

He found that a mortar, composed of common fat lime and eminently silicious sand, was not capable of acquiring any considerable hardness by exposure to the air. It is equally impossible to dispense with the use of sand; for if this species of lime, slacked and used without addition, is capable of hardening considerably by setting, it could not be actually employed in this way, except in very thin layers, and if it were attempted to use it thus as a mortar it would fall in fragments from the trowel. The presence of sand in some degree eludes the entire contraction, by subdividing it into an infinity of partial contractions, which take place in each interstice, formed by three or four contiguous grains: whence the pulverulent appearance, the permeability to moisture, and the weak cohesion which we have so often to regret in the mortar of our common edifices.

(477.) *On the best size of the grains of sand.*—Pliny and Vitruvius recommend that it should be clean, large-grained, and sharp. The sand which is made use of in London is very defective, being composed of round grains, and soiled with a large mixture of clay. Its fineness and smoothness cannot be amended; but by washing it well, the clay might unquestionably be got rid of, which would be a great improvement. Mr. Smeaton has shown by direct experiment that mortar of the best quality, when mixed with a small proportion of unburned clay, never acquires that degree of hardness which otherwise it would have attained.

Screened rubbish and scrapings of roads, consisting chiefly of gravel reduced to fine powder, are also used as substitutes for sand, but with great impropriety.

Mr. Rondelet says in his Treatise that mortar made with too fine sand never acquires the same degree of consistence as that made with moderately coarse sand; but it is probable that this refers only to mortars made with ordinary limes.

M. Vicat, however, did not find in his experiments much difference produced by the size of the grains of sand on the hardness of mortar, the greatest difference not exceeding one-fifth of the whole resistance.

With eminently hydraulic limes he found the order of tenacity to be greatest with fine sand, second with unequal grains produced by the mixture of the fine and coarse sand, and third with coarse sand.

Machinery.

Properties
of sand.

Manufac-
tures.

For the common hydraulic limes the order is: first, mixed sand; second, fine sand; third, coarse sand; and for common limes is, first, coarse sand; third, fine sand.

The conclusion that may be drawn from the results is, that the more the quartz is divided the more intimately it will combine with the highly hydraulic limes, on which it seems to exercise a great chemical action, whilst the reverse seems to take place with the common limes.

The sand used by the Romans is of various descriptions. In their building at Cahors they have used for their mortar a mixture of common sand and gravel, when an abundance of each was at their command; in other parts of France, where the lime is but of a middling quality, they have used only gravel; and in Syria there are examples of various hard ancient Roman mortars composed of very fine sand.

Best pro-
portion of
lime and
sand.

(478.) *The best proportion of lime and sand* in the composition of mortar is a point by no means settled. The Roman builders were accustomed to allow three parts of pit sand or two parts of river or sea sand to one of lime. In general, it may be affirmed, that it will be advantageous to use the largest quantity of sand that can be introduced, preserving the necessary degree of plasticity. Mortar, in which the sand predominates, requires less water in preparing, and therefore sets sooner; it is harder and also less liable to crack in drying than that in which the lime prevails. Smeaton observes, that there is scarcely any lime but what, if well burned and beaten, a load or measure of unslacked lime will take two loads or measures of sand. On pursuing this subject, he found that by good beating the same quantity of lime would take in one measure of tarras three of clean sand, which seems to be the greatest useful proportion; for on a further increase of the quantity of sand, the mortar requires so much more beating to bring it to a proper consistence and toughness, that the labour became of more value than the saving of materials. These observations agree very nearly with the experiments of Dr. Hutton.

Our ancestors have left us a crowd of incontestable examples that they well understood the Art of making cements. M. Vicat, however, considers that the very general notion that the Art is lost is entirely a mistake, and that mortars can be made without the use of puzzolana, at least equal in hardness to the best of the Roman.

A few years ago there existed at Agen the ruins of a bridge, thought to be antique on account of the hardness of the mortar, which was so great that they were obliged to employ blasting to remove the remains of the foundation. This bridge, however, which the lovers of the marvellous were inclined to carry back to the time of the Pelasgi, was built by a Charter obtained from Richard I., King of England, who was at that time master of Agen and a great part of the South of France. The mortar of the bridge of Valentré, built at Cahors in 1400, resembles in every respect, both in the quality of the lime and size and proportions of the sand, that of an ancient theatre whose ruins still remain in the same town at five or six hundred yards from the river.

On Cements exposed to the Action of Water.

(479.) Although a well-made mortar composed simply of sand and lime, if allowed to dry, becomes impervious to water so as to serve for the lining of reservoirs and aqueducts; yet if the circumstances of the building are such as to render it impracticable to preserve it from the action of the water for a sufficient length of time, the use of common mortar must be abandoned.

Cements
exposed to
the action
of water.

Among the nations of antiquity, the Romans appear to have been the only people who practised building in water to any great extent. The bay of Baiæ, like our fashionable watering-places, was the summer resort of all the wealthy of Rome, who not content with erecting their villas as near the shore as possible, were accustomed to construct moles and form small islands in the most sheltered parts of the bay, on which, for the sake of the grateful coolness of the sea, they built their summer houses and pavilions. They were enabled to build thus securely in the water by the fortunate discovery of puzzolana, which substance or some other possessing the same chemical property, is an essential ingredient in cements to give them the power of setting under water.

Before the introduction of puzzolana as an ingredient of the mortars of this Country, a substance termed *tarras* was imported from Holland for that purpose which is made use of by the Dutch, who have practised building in water to a greater extent than any other nation in Europe. It is nothing more than wacke or cellular basalt, and is procured chiefly from the Bocken-heim, Frankfort on the Maine, and Andernach, whence it is transported down the Rhine to Holland.

Various substances besides these are to be found in England, which give cements the property of setting under water; in fact, all the ferruginous clays, ochres, bluish schists, lavas, ferruginous sandstones, possess it in some degree. In the following Table are given the component parts of the substances most commonly used in this Country.

Compounds
of different
cements.

Manufactures.

Name of the substance.	Parts of silice.	Parts of alumine.	Parts of carbonate of lime.	Parts of oxide of iron and manganese.	Parts of magnesia.	Total.
Puzzolana	38	41	6	15		100 parts.
Common basalt ..	46	30	10	8	6	100
Amorphous basalt	47.5	32.5		20		100
Parker's cement ..	22	9		13	55	100 grains.
Loftus' cement ..	25.5	5		10.5	55.5	100
Mulgrave cement.	21.5	7.5		13.5	55	100

It should be here observed that the limestones which produce what we have termed hydraulic limes, contain these substances, combined with them in a small proportion, so that they will harden under water: a further addition of the above substances, however, in all cases improves their quality.

Mr. Smeaton, when engaged in the erection of Eddystone lighthouse, made a set of experiments in order to form a cement proper for that undertaking, the peculiar difficulties of which required one of the most perfect quality.

Smeaton's experiments.

(480.) The manner in which he made the experiments, was by mixing together as many of the ingredients as would form a ball of two inches diameter, which was allowed to set to such a consistence as not to yield to the pressure of the fingers, and placed in a vessel of water so as to be entirely covered; and being left there for a considerable time, he judged from the action the water had upon it how far it was calculated for his purpose.

Balls of common mortar tried in that way immediately dissolved, and those of two parts slacked lime and one of tarras would not always stand the test, but when made of equal measures of lime and tarras, they stood it very well. He tried in this way a variety of different limes mixed in various proportions with tarras, puzzolana, minion, &c., and ultimately decided upon equal parts of blue lias, lime, and puzzolana to be the most perfect composition for water cements.

In the course of his inquiries he was led to the following opinions.

That the degree of calcination of limestones was not of material importance.

That the water cements are equally good made with salt water as with fresh; or if any preference, it is in favour of the salt water. That lime made from soft limestones or chalk was equally good with that made from sand limestones. That although the practice of beating mortar well up is an advantage where common lime and a small quantity of tarras is used, yet where tarras is not spared and the lime is of superior quality, the repetition of beating appears not to be material.

That puzzolana and lime mixed with water so as to be in a perfectly fluid state, would settle to the bottom and become perfectly hard. This was important in enabling him to obtain a perfect grout for the vertical joints of the masonry.

That minion, which is a substance found very commonly with iron ore, when mixed up with equal parts of cement, is much harder than lime, but inferior to lime and puzzolana.

Mr. Smeaton has given the following Table of the proportions of the ingredients of a variety of cements, which may be used in different situations according to the facility of obtaining the materials.

The author makes the following observations on the preceding Table.

1. Those that would make mortar according to the preceding Table, should know, that the materials are all supposed to be in a *dry* state when measured. Smeaton's observations.

2. That the lime is supposed to be thrown into the measure with a shovel with some *degree* of force; for if put in as light as possible, in the way to make the most measure of it, there will be a want of the real quantity, and if pressed down, the measure will contain considerably more than what can be expected in *purchasing* the material; and the same may be said of the puzzolana, the tarras, and the minion.

3. Respecting sand, it is particularly to be noted, that, if in a moist state, the real quantity is considerably less under the same measure than if dry, and that in an *uncertain* degree; and as moist sand is most frequently bought for use, it is advisable that the operator should take a means of finding the difference of the proportion, and allowing accordingly in measure.

4. It should also be observed, that if the sand is not naturally a composition of *fine* and *coarse*, it should be rendered so by a mixture of different sorts; the proportion of *one* to the *other* need not be much studied.

5. The due beating of the mortar is, however, of *great* consequence; and without going into that repetition of beating, which has been always looked on as essential to the making the common tarras mortar, such as No. 11, a degree of beating sufficient to give it all *possible* consistence and substance before it is used, is in reality *indispensable*. And the method that has been found to answer the end in the most satisfactory way is to mix the due proportion of the lime and the puzzolana, the tarras, or the minion, together in dry powder; and it will also be well to have at least one-third of the *sand* (either fine or coarse) likewise dry. Put as much water in the lime, as that with a shovel or beater you can bring it to a paste of a moderate consistence, but rather more wet than to be properly used as mortar in that state; then by degrees beat in the moist

Manufac-
tures.

sand, and afterwards the dry, bringing it to a consistence by beating after every addition. The dry sand is intended to take up the superfluous moisture, so as to render the mortar immediately fit for use; and if this has not brought it to a sufficient stiffness, you may let it be till it inclines to set, and then beat it up to the due consistence; or, if immediately wanted, you may beat in a little dry lime powder to drink up the superfluous moisture; always, however, *faithfully* remembering not to terminate the beating till the mass has got *all* the toughness that you find it will acquire by beating. This method fully answers where *water lime* is concerned.

6. The customary allowance for tarras mortar beating, first and last, is a day's work of a man for every bushel of tarras; that is, for two bushels of lime powder with one bushel of tarras; so that, by No. 11, if a labourer's day's work (as at London) is rated at 2s., then, the bushel of tarras being valued at 4s., the beating will be half the price of the tarras; and the mortar produced being only $1\frac{1}{3}$ cube feet, the beating of the mortar will therefore amount to $14\frac{1}{2}d.$ per cube foot; whereas, in the way just mentioned, a man in half a day will beat to a very good consistence the whole produce that can be made, in any of the articles, from two bushels of *lime*; so that the beating of the best face mortar, as No. 4, being $4\frac{2}{3}$ cube feet, will be done for less than $2\frac{1}{4}d.$ at the same rate of labour.

Vicat on
water
cements.

(481.) M. Vicat also made a number of experiments on water cements, of which the following is an abstract.

His method of making of the experiments differed from that employed by Mr. Smeaton in the employment of conical glasses about three inches in diameter and four inches in height, which he filled with the composition instead of making it up into a ball. He ascertained the time each specimen required to harden to such a degree as to bear the weight of a polished steel rod filed square and loaded at the top, without visible impression. He also tried the comparative hardness in each specimen by observing the depth a steel rod was buried into it by a regular and constant percussion.

The following Table will give the results of his experiments on various compositions, immersed one year in water.

Lime slacked by immersion and powdered.		Granite sand.	Brick cement.	Days required for the mortars to harden so as to support a steel point loaded with a certain weight.	Relative resistance of each mortar after one year's immersion.
Common and very fat.	Middling and hydraulic.

By the term brick cement, we understand M. Vicat to mean calcined ferruginous clay. Machinery.

It will be seen here that within moderate limits, according to the circumstances and the nature of the materials, a due attention to their respective proportions may go so far as to affect the resistance of the mortar tenfold. In general, the influence of these proportions is the most powerful when the lime and puzzolanas or bases have the least energy of action.

The results of various other experiments by the same author may be comprised in the following statements.

With respect to the proper degree of calcination for different puzzolanas, which term he employs for the basis of all water cements:

1. That the first degree of calcination is the fittest for clay and ferruginous sandstone, and that the energy of these substances, as water cements, rapidly diminishes as they approach the state of vitrification.

2. That pit coal reduced to ashes by a slow fire is preferable to that in the state of scoriæ whether hard or friable, light or heavy.

3. That blue schist requires such a heat as will swell it.

4. That basalt should be fused.

It is particularly when these substances are combined with a common very fat lime, which of itself scarcely resists water, that efficacy as water cements is the most seen to depend on the degree of their calcination.

5. That an excess of lime in water cements retards the setting. The proportions the most favourable to speedy setting, are also those which ultimately give the greatest hardness.

6. That the most active puzzolanas combined with the common fat limes set sooner than with the hydraulic limes; but the latter with the most middling puzzolanas are the most active of all; and that the second method of slacking lime (as described in the former part of this notice) generally appears preferable to the first mode for speedy setting.

7. That water cements made with common lime make more progress in hardening from the second to the third year, than from the first to the second.

8. And that the cements made with the highly hydraulic limes have acquired nearly their utmost hardness at the end of the second year.

(482.) Mr. Brunel, previous to the commencement of the operations in the Tunnel under the Thames, made some experiments in order to ascertain the absolute strength of Roman cement in the following manner. Mr. Brunel's experiments. Pl. xxxvii. Fig. 3.

The bricks were stuck against a wall, as represented in fig. 3, plate xxxvii. on the face of each other, so that they sustained their horizontal position entirely by the strength of the cement.

1st Experiment with Francis and White's cement mixed without sand.—Thirteen bricks were sustained, the two at C were added by way of weight, then four at B, when in placing the last the arm broke at A.

2d Experiment, fig. 4.—Twelve bricks were fixed in the same manner; nine bricks were added as here represented, and left in that state without breaking. Both these experiments were made some weeks after the bricks had been fixed to the wall. The cement was therefore perfectly dry.

3d Experiment with Turner and Montague's cement.—In two hours, eleven bricks supported themselves in the manner above represented, and some weeks after twenty-one bricks were placed at the extremity, which broke it.

4th Experiment.—In two hours and ten minutes,

Manufactures.

eleven bricks supported themselves placed edgewise, and several weeks after four more were added at the extremity, which broke the arm at two bricks from the wall.

In none of these experiments has the cement broken off; it is invariably the brick, or the want of complete adhesion to the surfaces of the bricks, that has occasioned the fracture.

Other experiments were made with Weston's Roman cement. Two piers six feet long and fourteen inches square were constructed, one with pure cement, and the other with half cement and half sand. When dry they were laid transversely on props, and were supported three inches from each end and loaded in the middle. At the end of a fortnight a weight of eight hundred and ninety-six pounds was placed on each of them, which broke that built with the sand and cement in half an hour after, but the other continued to support the weight.

Mr. Brunel made some other experiments on this sub-

ject; for a description of which we refer the reader to Machinery. the third edition of Barlow's *Essay on the Strength of Timber and other Materials*.

Mr. White also has made similar experiments on the strength of mortars composed of different proportions of puzzolana, which will be found in No. XXXIX. of the *Quarterly Journal*.

Colonel Pasley and other authors, besides those whose labours we have described, have written on the subject of cement; among whom Dr. Higgin's name stands very high. We have, however, omitted to give a description of his experiments: in the first place because the proportions being made by weight instead of by measure, are apt to lead to error; and in the next because his results do not differ materially from those of Mr. Smeaton, to whose Reports we have been greatly indebted, as also to an excellent article on M. Vicat's experiments in the *Repertory of Arts*.

Colour-mills.

Colour-mills.

(483.) These are made use of by painters, dyers, &c. for reducing the matters which they employ in colouring into a fit state for use. They are, of course, varied in their construction, owing to the different nature of the substances from which the colour is obtained. The colours employed by house painters, which are not required to be very fine, are ground with oil in mills with horizontal stones similar to corn-mills, or by merely passing them several times between two horizontal rollers, these being each time adjusted so as to be nearer to each other.

For artists, who require their colours ground to a very high degree of fineness, a marble slab and pebble muller are generally employed, and water is mixed with the matter while grinding instead of oil. The use of water is preferred, because it allows the colour to grind more freely, and consequently to be more readily reduced to a fine state, and at the same time combines with the dirty and impure parts of the substance, which by this means can be separated from it; but this method of grinding colours is found very injurious to the health of the workman, from the position he is obliged to stand in to work, which causes him to inhale the volatile parts of the mixtures, which are sometimes very noxious, particularly when litharge of lead is mixed with the water, a custom not unfrequent.

A mill to remedy this evil was projected by Mr. Rawlinson of Derby, who received a medal from the Society

of Arts for his invention, which consisted of a marble roller working inside a concave marble muller, which covered one-third of its circumference. By this means the paint could be brought much oftener under the muller in a given space of time, and consequently a greater quantity ground than by the usual method above described.

Fig. 3. pl. xxxvi. is an elevation of the Machine: A is a roller or cylinder, made of any kind of marble; black marble is esteemed the best, because it is the hardest, and takes the best polish. B is the concave muller, covering one-third of the roller made of the same kind of marble; it is fixed in a wooden frame *b*, which is attached to the stand or framework of the Machine at *l*; *h* is a piece of iron about an inch broad, which is used to keep the muller steady. It has a small binding screw with a fly nut at *c*, which is for the purpose of laying more pressure on the muller if required, as well as to keep it steady. D is a scraper made of a clock spring, about half an inch broad, fixed in an iron frame. It turns on pivots *d d*, so that when in use the scraper lies in an inclined direction against the roller, and at other times it is turned back out of the way.

G is a slide board, made to draw out, which catches any particles of paint that may occasionally fall from the muller; upon this board is placed the plate H, to receive the paint as it falls from the scraper. F is a drawer, used to contain currier's shavings, which are said to be the best things for cleaning paint-mills.

The colours ground by this mill require to be pre-

Rawlinson's
colour-mill.
Pl. xxxvi.
Fig. 3.

Manufac-
tures.

viously finely pulverized in a mortar; they are then applied by means of a spatula or palette-knife to the point of the roller above the scraper, and the roller is turned round by means of the winch handle G, until the colour, by passing between the revolving stone and muller, is sufficiently reduced, when the scraper D, which during the operation lies back, is inclined against the stone, and the winch handle is turned the reverse way for a few revolutions in order to scrape off the colour, which falls into the dish H.

The quantity ground at once is regulated by the state of fineness to which it is required to be ground: if it is wanted to be very fine, it must be put on in small quantities and ground for a great length of time.

When the colour is ground, it is tied up in bladders for use. Mr. Rawlinson recommends instead of drawing up the neck of the bladder close, which is the common custom, to insert a cylindrical stick, and bind the bladder close round it, which, when dry, will form a tube or pipe, through which, when the stick is withdrawn, the colour may be squeezed out as wanted, and the neck again closed by replacing the stick. This is certainly a neater and much more cleanly method than the usual one of tying the neck of the bladder close, and perforating it when any paint is wanted.

The barrel of a quill may be tied in place of the stick into the neck of the bladder, with its closed end outwards, which will keep the paint secure in travelling, and when used, the end of the quill being cut off, it may afterwards be closed by a stick.

Indigo and other vegetable colours are ground dry in a mortar made of marble, or hard stone, nicely formed and polished, by a muller or grinder, nearly in the form of a pear, in the upper part of which an iron axis is firmly fixed, which is bent in the form of a crank, to serve as a handle for turning the muller: the axis is inserted when in use into two collars, so as to revolve easily and truly in the axis of the mortar. The muller has a slit or groove made through it, almost dividing it into two parts, which is useful in collecting the colour while grinding, and bringing it continually under the muller. A circular board in two halves, with a centre hole to fit the axis, is used to lay over the mortar to prevent the dust of the colours from flying out. By means of a weight, any required pressure may be added to the revolving stone.

Preparation
of indigo.

Pl. xxxvi
Fig. 4.

(484.) The mills employed by dyers for effecting the solution of indigo with the liquid with which it is mixed are differently constructed. In this process trituration or friction is as much as possible avoided: in the first place to prevent the loss of material; and in the next the inconvenience arising from the chemical action of the substance upon which it is rubbed. Fig. 4 is the elevation of a mill very commonly employed in small dye-works, intended to be worked by a man or a boy. In this Machine, the pulverization or granulation of the indigo is effected by the pressure of a number of smooth cast iron balls, like those for cannon, which, being rolled among the indigo, press it into a paste by their weight, until it unites with the liquid by which it is to be held in solution.

A is the vessel which contains the indigo, which is of a cylindrical figure; and B is an upright spindle, upon which a wheel C C is fixed, having a convenient number of arms projecting round the vessel like the radii of a circle; and below each of these arms are attached pieces of iron, which engage the balls, and cause them to revolve with the wheel. By this means, when the

wheel C C is turned, all the balls in the vessel A are set in motion, which by rolling over the indigo gradually press it until it unites with the water or liquid with which it is surrounded. The mill is moved by a handle D, upon the axle of which is a pinion which engages the bevelled wheel E upon the vertical spindle of the rolling wheel C. F is a cross bar, with balls at the end, which serves as a fly regulator to the motion of the Machine.

When the indigo is found to be sufficiently dissolved and united with the water, the liquid thus formed is drawn off in any other vessel for use by means of a vent and spigot placed in any convenient part of the bottom of the vessel.

This Machine, although very ingenious, is not suited to works on the large scale, where much indigo is consumed. In such cases, steam power is generally employed to work the indigo-mills, and they are constructed so as to require no attendance except to empty the vessel when the indigo is sufficiently mixed, and to add a new supply. A semicircular vessel of cast iron is placed upon a strong wooden frame, having a cover made in two pieces, with a circular aperture to admit an upright shaft, which descends to the bottom of the vessel, and the upright shaft is jointed to a horizontal shaft of wood, the other end of which is connected with a crank driven by the steam engine, whereby a reciprocating or alternate motion is given to the upright shaft, which sets in motion iron cylinders in the body of the vessel, and produces the same effect in grinding and mixing the indigo as the balls in the Machine first described. The cylinders may be made of any diameter or length which is found convenient, and the greater the mass of iron they contain, the quicker and more effectually will be their operation upon the colouring matter, provided there is a sufficient power to drive them. As this Machine requires no attention whatever, it is found very useful in large dye-works, as by means of it the men can constantly command a large supply of prepared indigo, which may be drawn off when wanted. It is also advantageous, because the longer it is under the preparing process, the better in every respect: fresh indigo is of course added as the supply gets low.

(485.) Among the colour-mills employed by dyers must be included those made use of for preparing logwood, madder, and other woods, for the process of infusion, by reducing the material into very small pieces or shavings, which, of course, expose a greater number of particles to the action of the water, and by this means the dyeing property is more readily extracted from them. Mills for this purpose require considerable power, and are therefore generally worked by the steam engine. They are at the same time very simple in their construction, consisting of a horizontal shaft put in motion by Machinery, upon which a cast iron circular wheel or plate is attached so as to revolve very truly in the plane of its motion. This plate has a plane or cutter attached to it so as to project as much above the surface as it is required to have the shavings in thickness. The axle has a bearing immediately in front of the revolving plate, upon a part of the framework of the Machine; this framework has also attached to it a hollow piece of cast iron, the opening of which leads in an inclined direction to the plate, and to such a part of it that the cutter or plane passes the end of the square opening every revolution of the wheel. The log or other wood to be cut is passed down the inclined cast iron tube, and forced by the workman against the surface of the

Machinery

Preparation
of logwood.

Manufac-
tures.

Machinery

Pl. xxxvi.
Fig. 5.

revolving plate or wheel. The Machinery being thus put in gear, a shaving of the wood is taken off by each revolution of the cutter as it passes the end of the tube.

In large works, where a great quantity of logwood is required to be cut, this method does not answer so well, as an attendant is required to each log, which consumes a great deal of labour. In such cases the mills are generally so constructed that one man can attend to several logs at the same time. Fig. 5 is a plan of a mill very commonly employed in large works. A A A A is a strong wooden framework which supports a platform C C. B is the cutting barrel, which is made of wood with cutters round the circumference; it has bearings in plumber blocks attached to the framework A, and is put in motion from the Machinery by the spur wheel D. The platform is placed in an inclined position, and in such a direction with respect to the wheel that the logs meet it at an angle with the circumference. The logs are seen at L L; they are attached to a frame E E, which is moved forward by the racks and pinions R R, P P. The action of the Machine will thus be readily understood. The logs being fixed in the movable frame, and the Machinery put in motion, the attendant, by the racks and pinions, forces the end of the logs against the wheel, which by its revolution cuts off little chips or shavings, which fall into a proper vessel placed beneath to receive them.

Preparation
of woad.

(486.) Woad, which is a shrub grown in some parts of England, from which the colouring matter of the same name is obtained, undergoes several processes to prepare it for the dyer. The plant is conveyed to the mill in carts, which are so contrived as to be lifted from their axle, and raised by a crane so as to deposit their contents in the upper floor of the mill. In this floor there are holes through which the plants are passed to be conducted to the grinding wheels, which are about three feet in width, and constructed with iron bars on their circumferences, for the purpose of crushing the woad; they are fixed eccentrically on their shafts, so that their diameter is greater on one side than the other. The bruised woad is thrown into rooms on the sides of the mill, destined for its reception, by means of shovels, where it remains until the juice is so much drained off as to leave it in proper condition for being formed into balls, which is done by labourers with an apparatus for the purpose. It is laid upon trays, to be conveyed to the drying ranges, where it is kept until sufficiently dry, and then laid by until the whole crop has undergone the same operations, and the workmen are ready to manufacture it.

To prepare it for use in the Art of dyeing it is necessary it should undergo a proper degree of fermentation, which is accomplished in the course of seven or eight weeks. This is termed, in the technical language of the Art, *couching*. It is effected by regrinding the balls in the same mill as before, to a fine powder, and then spreading it upon the floors of the room in which the balls were formed, to the thickness of about three feet, where it is then moistened with water to keep it in a proper slow state of fermentation, and so managed by turning that it may pervade the whole in an equal manner. In this business the direction of an experienced workman is necessary, as, in the turning, it is of much importance that the parts of the materials be perfectly divided, which can be effected only by a nice management of the shovel. It is also stated, that much advantage has been found

in the goodness of the woad from the drying and storing being performed in a careful manner. When this attention is neglected, the woad will not, on being broken between the finger and thumb, draw out into fine hair-like filaments, or in the technical language of the manufacturer, *beaver well*. A proper attention to this particular state of the woad is necessary, as the use of this substance in the blue vat of the dyer is not merely to afford the colour of the plant, but by bringing on a very gentle fermentation to excite the indigo in the same vat to yield its colouring principle more perfectly.

When the heat in the process of couching has gone too far, the substance will be what is termed *foxy*, and when it has not proceeded to a sufficient degree, it will be what is termed *heavy*; when the material be good, it will not soil the fingers by being rubbed on them. In the conclusion of the process, the cooling is effected in so gradual a manner as to render it not liable again to ferment; and it is of course proper for being preserved in casks, or in any other way; being then ready for use.

The preparation of woad as practised in France is rather different. The plant puts forth at first five or six upright leaves, about a foot long and six inches broad. When these hang downwards they are considered fit for gathering: five crops are gathered in a year. The leaves are carried directly to mills, which are sometimes made with running stones, like an oil-mill, or with a grinder, similar to a bark-mill, and there ground into a smooth paste; but if this process were deferred for any length of time the leaves would putrefy. The paste is laid in heaps, pressed close and smooth, and the blackish crust which forms on the outside is immediately united if it happens to crack; for if this were neglected, little worms would be produced in the cracks, and the woad would lose a great part of its strength. After lying for sixteen days the heaps are opened, the crust is rubbed and mixed with the inside, and the matter formed into oval balls, which are pressed close and solid in wooden moulds. They are then dried upon hurdles: in the sun they turn black on the outside, and in a close place a yellowish colour, particularly if the weather be rainy. The dealers in the article prefer it in the former state, although it is said the workmen find no great difference between the two. Good balls are distinguished by their being weighty, of an agreeable smell, and being within, when rubbed, of a violet colour. For the use of dyers, these balls require a further preparation. They are beaten with wooden mallets on a brick or stone floor into a gross powder, which is heaped up in the middle of the room to the height of about four feet, a space being left for passing round the sides; the powder, moistened with water, ferments, grows hot, and throws out a thick fetid fume; it is then shovelled backwards and forwards and moistened every day for twelve days; after which it is stirred less frequently, without watering, and at length made into a heap for the dyer.

Astruc proposes the manufacturing of fresh woad leaves in Europe after the same manner as the indigo plant is manufactured in America, and thus preparing from it a blue fecula similar to indigo, which from his own experiments he has found to be practicable. Such a management would doubtless be accompanied with some advantages, though possibly woad so prepared might lose those qualities which now render it in a large business preferable on some accounts to indigo, as occasioning greater despatch when once the vat is ready,

Manufac-
tures.

and giving out its colour less hastily, so as to be better fitted for dyeing very light shades.
The immense extent of dyeing substances exported

and imported, and its growing increase, will be seen by Machinery the following Table.

(487.) *An Account of the Quantities of the undermentioned Colours used in Dyeing, Imported into and Exported from the United Kingdom, the Quantities cleared for Home Consumption, and the Net Produce of the Duty thereon, in each Year, commencing 5th January, from 1820 to 1831, both inclusive.*

Corn or flour-mills.

History of corn-mills.

(488.) The history of the invention of grinding corn is nearly the same as the history of mills, these having been for many Ages devoted to this one single purpose; but in the early states of Society the mill employed in this duty, if indeed such means as were had recourse to for grinding at that time deserve the name of mills, were of the most simple kind. Arthur Aikin, Esq., Secretary to the Society for the Encouragement of Arts and Science, has been at great pains in collecting from different sources historical facts relative to the form and opera-

tion of the most ancient kind of mills, and we are much indebted to him for obligingly supplying many of the following particulars. The Ancients prepared their corn for grinding, by first exposing it to a degree of heat sufficient to render it brittle, and in part to separate the husk from the grain. It was then placed in mortars and rubbed gently with a pestle, sufficiently to separate the husk, but not enough to bruise the grain, which, without some care, would have been done, the corn having been already made brittle by scorching. Such, according to Pliny, was the method practised by the ancient Romans, particularly in those grains whose husk adhered too firmly to the seed, to be removed by simple rubbing. The same mills which thus served to decorticate their barley, answered also for reducing it and their other grains to powder or flour, especially as they had been rendered brittle by toasting; but corn which has been toasted is not afterwards susceptible of fermentation, and therefore so long as the Romans adhered to this mode of preparing their grain, which was introduced by Numa, (and represented by him as a kind of religious duty,) it was impossible that they should have any other bread than mere cakes or biscuits of baked dough.

Both mortars and pestles were at first made of wood, no doubt the hardest and most compact that could be found; this material was afterwards superseded by stone, and the Etrurians seem to have given the mortar a

Manufac-
tures.

deeper and more cylindrical form than usual; they likewise furrowed the sides with longitudinal scores, and cut the bottom into rays like a star; that part of the pestle which entered the mortar was rough, and was terminated by an iron spike, intended, probably, to be placed in a hole in the centre of the star just mentioned; the pestle was worked in an upright position, and seemingly by a rotary movement on its axis. This mortar, or mill, as it may without much impropriety be called, was intended, however, only to husk the grain, not to reduce it to powder.

Roman
hand-mills.

If the corn-mill generally used in Italy, in the later times of the Roman Republic, and during the reign of the first Emperors, were of the same form as those which have been found at Pompeii, it is evident that the Italian corn-mill differed entirely from that used in Greece and in Asia, being in principle nothing more than the Etrurian mortar reversed. It consists of a stone post (the pestle) fixed in the ground, and terminated by a cone having its point cut off; a hollow cone, (the mortar,) also with its point cut off, is laid upon the solid one, and the sides of the former being somewhat less sloped than that of the latter, it is manifest that they will touch only by their lower edge, and from that part will diverge upwards, leaving an angular space between them, the width of which will be regulated by the difference of slope in the exterior and interior cones: this space will be the grinding surface. To the upper part of the outer cone is fixed a funnel-shaped hopper, and two opposite horizontal beams also project from it, to which are attached the animals by whose strength the mill is turned. The corn being delivered from the hopper into the space between the two cones, is there ground by the rotation of the outer one, and the meal drops out at the bottom where the edges of the cone come in contact. At first the labour of slaves in general was employed to work these mills, but it was afterwards specially imposed as a punishment on refractory ones; next, asses, cattle, or horses were used, generally the first-named, the size of the mills not requiring the work of two horses, and being more conveniently wrought by two animals than by one. The discontinuance of the use of slaves in mills is stated to have occurred about the end of the IIIrd Century, in the reign of Theodosius; this however, in all probability, applies only to public slaves. It does not appear that hand-mills, on this or any other construction, were in use among the Romans. The material of the mills found at Pompeii is a black cellular lava, such as is used at present for the same purpose in that part of Italy; but other stones, both harder and softer than this, were also employed.

Hand-mills originated in the East, at a period preceding that of the earliest historical records. Three measures of fine meal kneaded and made into cakes on the hearth form part of the hospitality of the Patriarch Abraham. (*Gen. xviii. 6.*) Mills, therefore, for grinding corn were already in use; and that these were hand-mills, we may be assured, because the Jewish people seem never to have employed any other kind, and because, even to the present day, the Arabians and inhabitants of Syria, though not entirely without cattle-mills and water-mills, in some of their largest towns, seem generally to retain the old custom of grinding their corn at home, and thus making it a regular daily domestic occupation. Working at these hand-mills has for the most part fallen to the lot of the women; and, as it is both irksome and laborious, it devolves of course to

the slaves, but only to the lowest classes of them in opulent families. It was quite accordant with the simplicity of ancient times, that the wife of the Patriarch, a man rich in servants and in cattle, should herself prepare the bread for his guests, but it would have been quite out of character to demand from her the servile labour of grinding at the mill. In ancient Egypt, the same kind of hand-mill seems to have been used, and was worked also by the lowest class of female slaves. So exclusively was this labour appropriated to them that, in order to comprehend every rank of the Egyptian people, we find the Historian making use of the expression, "from Pharaoh, that sitteth on his throne, to the maid servant that is behind the mill." And the Jewish Prophets employ the same figure as testifying the lowest state of degradation: "Virgin daughters of Babylon, thou shalt no longer be called tender and delicate, but shall sit in the dust, take the mill-stones and grind meal." Criminals and public slaves, when treated the most harshly, were condemned to the mill; thus, Samson, when made captive, and blinded and fettered, was set to grind in the prison-house. Generally one, but sometimes two persons were employed at each mill, which consisted essentially of two flat stones, the lower one the hardest and probably also the heaviest.

In many respects, the customs of the Oriental people seem to have undergone hardly any change; and modern travellers inform us, that hand-mills are still in use very generally, and of a form and construction differing in no respect (as far as we can judge) from the ancient ones. Dr. Shaw, in his *Travels in Barbary*, says, "Most families grind their own wheat and barley at home, having two portable millstones for the purpose; the uppermost whereof is turned round by a small handle of wood or iron, that is placed in the rim. When this stone is large, or expedition is required, then a second person is called in to assist; and it is usual for the women alone to be concerned in this employment, who seat themselves opposite to each other with the millstones between them."

The observations of Sir J. Chardin are to the same purpose. "In the East," says he, "they grind their corn at break of day, and when one goes out in a morning, one hears every where the noise of the mill. The employment is extremely laborious, and esteemed the lowest in the house, about which they set their black servants only, and such as are the least fit for any thing else." Hand-mills of precisely the same form and construction are at present used in India; a specimen of which is deposited in the East India Museum.

Greece received its earliest civilization from Asia and Egypt; and the tradition which preceded the Poetical History of that Country, alludes to the first introduction of agriculture, and to the substitution of corn for acorns and other wild productions of the forest. Bread and flour are frequently mentioned by Homer, the earliest of their extant writers, and, consequently, imply the existence of corn-mills. If we were entirely destitute of any account of the mill used in those times, we should yet be justified in supposing it to be the same as that in use in the Countries from which the Greeks derived their knowledge of corn: but what, in such circumstances, would only be a very probable conjecture, is reduced to matter of fact by two passages in the *Odyssey*; a Poem at once delightful from its narrative, and invaluable as a record of domestic life in what may be termed the semi-Heroic Age of Greece. The female servants of the Chief of Phæacia are represented as fifty in number, some of whom are

Machinery.

Oriental
hand-mil.

Manufac-
tures.

employed in turning the corn-mills. The mills also of Ulysses himself were twelve in number, turned by as many female slaves, grinding wheat and barley with great labour.

A hand-mill also, of the same form as the Oriental one, was for many centuries employed in the British Islands. It was called a Quern, and may possibly have been introduced by the Phœnicians, or by those Tribes, whoever they were, who first brought into the Country the Arts of Agriculture. Its use in the Western Islands of Scotland has been obsolete for hardly more than fifty years. It was worked by one or two women, as represented by Mr. Pennant in his *Tour in Scotland*. Shakspeare speaks of "labouring in the quern;" and Hakluyt, in his *History of Voyages and Travels*, mentions the use of the quern on shipboard, for grinding mustard seed. It was therefore no doubt made of various sizes, according to the use for which it was intended, and evidently was not entirely discontinued in England so late as the reign of Queen Elizabeth.

Invention
of water-
mills.

It is not known to whom the invention of water-mills is owing. Strabo, in an obscure passage, seems to speak of one set up by Mithridates. There is, however, satisfactory evidence that a corn-mill driven by water was set up at Rome soon after the conquest of Mithridates by Pompey.

The novelty of the invention, and the anticipation of the benefits to humanity likely to result from its adoption, are expressed in a beautiful copy of verses by Antipater, a Greek Poet and contemporary, of which the following is a translation.

"Cease your work, ye maidens who laboured in the mill; sleep now and let the birds sing to the ruddy morning; for Ceres has commanded the Water Nymphs to perform your task. Obedient to her call, they throw themselves on the wheel, force round the axle, and thus turn the heavy millstone." A more scientific account of the Machine is to be found in the *Architecture of Vitruvius*, who probably lived in the reign of Augustus. From this Work we learn that the mill, that is the running stone, was supported on the end of an upright shaft which served also as the axis of a flat toothed wheel; this latter wheel worked in another fixed in the upper end of the great axis, to the lower end of which the water wheel was fixed. This latter, therefore, was horizontal or nearly so, and was turned round by the force of the stream in which it was immersed. As the Machinery of water-mills for grinding corn became improved, hand-mills, though not entirely abandoned, fell into great disuse. This, however, was occasioned not merely by the greater cheapness and expedition with which the former did their work, but also by certain rights and obligations imposed by the Feudal System on Lords of the Manor. The Lord was obliged to be at the expense of erecting a mill worked by water or wind for the use of his tenants; and they, in return, were obliged to take their corn to be ground at the Lord's mill, paying him a certain toll for the convenience.

Thus the interest of the Lord, or at least of the miller whom he employed, was directly concerned in discouraging the use of private mills, and in removing one of the strongest motives to excuses for domestic slavery.

Of wind-
mills.

The wind-mill, which is undoubtedly a much more recent invention than the water-mill, came afterwards into very common use; but both the date of its invention, and even the Country in which it was first employed, are uncertain.

Steam Flour-mills.

Machinery

Steam
flour-mills.

(489.) In the year 1783, the power of steam was first applied to the grinding of corn at the Albion Mills, erected at the Southwark foot of Blackfriars bridge. This erection was most unjustly calumniated in its day, under an idea that it was a monopoly injurious to the Public; a very erroneous notion, as it was the means of considerably reducing the price of flour while it continued at work. It was destroyed by fire in 1791; an occurrence which has been with great reason imputed to design. Since that time, however, a great many steam-mills have been erected for this purpose, being found to possess an advantage over wind-mills from their perfect regularity of motion; and in Countries where coal is cheap, they can even compete with them in point of expense. The operation of grinding, by whatever power, is now performed by two horizontal stones placed at a short distance one above the other; the lower being immovable, while the upper one turns upon a spindle, and has a hole in its centre through which the corn is admitted.

The opposed surfaces of the two stones which act to grind the corn are generally perfectly plane, although sometimes each is made slightly conical, the upper one which is hollow being made rather more concave, the lower one is convex, so that they come nearer together towards their circumference; by this means it is supposed the corn has a better opportunity to insinuate itself between them generally as far as two-thirds of the radius where the process of grinding begins to take place. In stones of six-feet diameter, when formed on this principle, the upper stone is made concave about one inch at its centre, and the lower one convex about three-quarters or five-eighths of an inch; but in smaller ones of from four to four feet six inches diameter, where the velocity or number of revolutions is greater, a much less hollowing is necessary; and in these cases, the lower stone is made perfectly plane, as, by reason of the greater centrifugal force, the corn has sufficient tendency to pass from the centre to the circumference of the stones without any fall being given.

When the corn has arrived at the point where the grinding begins to take place, it passes into furrows or channels cut into the upper and lower stone, made to cross each other after the manner of a pair of scissors, (as will be more particularly described below,) and being thus reduced to powder, it passes along the furrows to the circumference, where it is received into the hopper and passed from thence into sacks or into the dressing Machine, where the coarse and fine parts are separated for sale or domestic purpose.

(490.) In plate xxxviii. we have given a section of one of the wings of the flour-mill lately erected by Messrs. George and John Rennie, in the Royal William Victualing-yard, Plymouth, from which the general action of a flour-mill will be understood; we shall afterwards describe the various parts of the mill separately. This is one of the largest and most complete mills in England, and was only completed during the last year 1833. The building which contains it is nearly 240 feet in length, and above 70 feet in height. Each wing contains twelve pair of stones driven by a 45-horse power engine situated in the body or centre of the building. The stones are 4 feet 3 inches in diameter and make 123 revolutions per minute; each pair grinding about five bushels of corn in an hour, or, which is nearly the same,

Pl. xxxviii.
Description

flour-mill in
his Majesty's
Victual
ling-yard,
Plymouth.

Manufac-
tures.

the mill when at full work will grind upwards of 120 bushels in an hour by two 45-horse power engines, and at the same time work eight dressing Machines, and four screening or cleaning Machines for preparing the flour to be ground. The fly wheel of the engine which works the stones and dressing Machines in the right wing of the mill, is seen at *f* in the figure. *A A* is the main shaft of the engine, which has its bearings in plumber blocks bolted to the cast iron frames *a a*. It has attached to it two bevelled wheels *B B*, eight feet in diameter, which engage two smaller ones, of five feet four inches diameter, situated on the main vertical shafts *C C*, *C C*. The vertical shafts have bearings at the lower end in the cast iron frame *a a*, and in various parts of their length in plumber blocks or brasses attached to the floor of the mill. Their shafts are situated in the centre of a circular mass of brickwork *h h*, termed the hursts, which form the foundation of a strong cast iron framework *b b*, which supports the millstones and affords bearing to the Machinery employed to put them in motion. *D D*, *D D* are cog wheels of ten feet diameter attached to the vertical shaft *C C*, round the circumference of each of which are situated, at equal distances, six toothed wheels of small diameter, upon the spindles of the upper millstones, and which of course put them into very rapid motion.

The corn to be ground is deposited in the upper floor *E E*, in bins situated between the cast iron pillars *F F F*, and from which it is conducted by spouts to the screening Machines *S S*; the purpose of these is to separate the sand and other extraneous matter which unavoidably becomes mixed with the corn. They consist of a cylindrical sieve divided so as to resemble an Archimedes' screw, so that the corn being admitted at one end has, by the revolution of the cylinder, to pass over a great surface of wire, which takes from it the greater portion of the sand and dirt: when it arrives at the end of the Machine it falls into a hopper *h*, from which it is conducted by spouts *c c* to the millstones. One of these screening Machines will supply sufficient corn for six pair of stones. The hopper *h* will be observed to have two screening Machines, the object of which is, that the corn may be taken more conveniently from any part of the floor above. *d, d, d* are small hoppers supported by a wooden framing attached to the casing *m m* of the millstones, into which the corn is received immediately from the hoppers *h, h'*; *e, e, e* are spouts placed nearly in a horizontal position, which conduct the corn from the small hoppers to the eye of the millstone. They are attached to the hopper so as to admit of a slight horizontal motion, which is effected by a projected part of the axle or spindle of the stone termed the *damsel*. It is shaped like a cross, so that, by the revolution of the millstone, it keeps tapping the end of the spout *e* and gives a rapid vibratory motion to it, which causes a gradual and regular supply of corn to pass down to the stones. The flour or meal which comes from the millstones is conducted by spouts to the bins *G G*, situated on the ground-floor.

One of the main vertical shafts *C C* is continued up to the roof of the mill, in order to give motion to the sack tackle or Machinery by which the corn, after being ground, is elevated to the upper floor, to be passed through the dressing and bolting Machines, situated on the second floor, by which process the fine and coarse parts of the flour are separated from each other.

The sack tackle is very simple, and will be readily

understood from the drawing. It consists of a barrel *h*, Machinery situated on a horizontal shaft having bearings on the two beams of the roof; it receives motion when required by a system of wheelwork communicating with the bevelled wheel *g* on the vertical shaft. A rope is wound round the barrel and proceeds to the bottom of the mill, by which a sack of flour may be readily raised to any floor of the mill by merely putting the wheelwork in gear.

The dressing Machines and bolting-mills are situated at *G H*, on the second floor of the mill. The drawing being on so small a scale, we have not attempted to show any more than the box or casing by which they are surrounded to prevent the escape of the flour; but their construction does not differ from that of the common dressing and bolting Machines, which will be described in a subsequent part of this article. They are put in motion by a bevelled wheel situated on a horizontal shaft, running at right angles to the shaft *c c*, which can be put in gear with either of the bevelled wheels *w w* on the vertical shaft, in order that motion may be given to the Machines in either direction. The flour, after being divided by the dressing Machines into the different degrees of fineness required for the different purposes of the Navy, is conveyed by spouts to the lower floor, where it is received into sacks.

The floors are constructed in this mill of wood, and supported by cast iron pillars, but in the Deptford mill which has been since erected, Messrs. G. and J. Rennie have preferred the use of cast iron both in the floors and in the roof; which has not only the great advantage of superior durability, but that of rendering the mill perfectly secure against fire, an accident to which flour-mills are very liable.

We add here the following experiments showing the actual duty performed by his Majesty's mills at Gosport, Plymouth, and Deptford, which have been kindly supplied us by George Rennie, Esq.

(491.) *His Majesty's Royal Clarence Victualling-yard at Gosport, December 21, 1830.*

Experiment 1.—The steam engine equal to the nominal power of 45 horses, made by Messrs. Boulton and Watt, Soho. When the steam engine was set to work it was driving 8 pairs of millstones, each 4 feet diameter. One wire dressing Machine, dressing biscuit meal at the rate of 13 sacks per hour. One sack tackle at the end of the granary delivering a cargo of wheat to the top floor at the rate of about 120 sacks per hour, with the wheat screens and other Machinery necessary to perform the regular service of the mill. The produce of each of the 8 pairs of millstones was taken for 5 minutes. Also every other pair was taken for the same time, making the exact average rate of one pair for one hour produce 250 pounds, the wheat weighing 60 pounds per bushel; by adding one pound for evaporation in each bushel, this will be 254 pounds, making the average rate of grinding for each pair of millstones to be 4.23 bushels per hour, and the proportion of one bushel of coals to 6.52 of wheat; the coals were bad, name unknown.

Experiment 2.—One single wire Machine as under, dressed in the space of 9 minutes,

Biscuit meal	516 pounds
Pollards	26
Bran	70

Total 612

Experi-
ments on

ty's flour-
mills at
Gosport.

Manufac-
tures.

being at the rate of 12.3 sacks per hour; the whole being the produce of 69 bushels, or 8 quarters 5 bushels of wheat.

Llangennech coal was used; and in the space of $3\frac{1}{2}$ hours, 12 hundred weight, or 1344 pounds, or 18.16 bushels, or nearly at the rate of 5.2 bushels per hour, were consumed.

December 22, 1830.

Experiment 3.—At 20 minutes after 1 set the engine to work, supplied with coals from Lamb's Main, weighing 74 pounds per bushel, of indifferent quality. Driving 10 pairs of millstones. One wire dressing Machine with the screens, sack tackles, and other Machinery for the usual service of the mill. After working for the space of 2 hours and 42 minutes, the engine was found to have consumed 13 hundred weight, or 19.67 bushels of coals. Ground 70 hundred weight, or 132.84 bushels of wheat and dressing its production; this being the proportion of 6.76 bushels of wheat ground and dressed with 1 bushel of Lamb's Main coal. The dressing mill worked $1\frac{1}{2}$ hours.

December 23.

Experiment 4.—At 11 minutes past 8 A.M. set the engine to work, driving 10 pairs of millstones, the baking Machinery, wheat screens, sack tackle, and other Machinery necessary for the usual service of the mill. After working 3 hours there had been consumed 11 hundred weight 1 quarter 10 pounds, or 17.16 bushels of Llangennech coal, weighing 74 pounds each, in grinding 76 hundred weight 1 quarter 10 pounds, or 142.5 bushels of wheat; this being in proportion of 8.3 bushels of Llangennech coal, or $4\frac{1}{2}$ bushels of wheat per hour, for each pair of the millstones employed.

December 23.

Experiment 5.—Set the engine to work at 11 minutes past 11, driving 10 pairs of millstones, the baking Machinery, two sack tackles delivering a cargo of wheat, with other Machinery for the usual service of the mill. After working 3 hours, the engine had consumed 12 hundred weight 2 quarters 15 pounds of Durham coal, or 18.86 bushels, each weighing 75 pounds, and had ground 140 bushels of wheat, which is in proportion of 7.42 bushels of wheat to 1 bushel of Durham coal; and an average of 4.66 bushels of wheat per hour for each pair of millstones.

Royal William Victualling-yard, Plymouth, Monday, April 14, 1834.

At Ply-
mouth.

Two steam engines of 45 horse power, Boulton and Watt, diameter of millstones 4 feet 3 inches, make 120 revolutions per minute. Started the steam engine next the Basin at 22 minutes to 11, barometer 28. First, in order to clean sufficient wheat for the hoppers; this occupied half an hour. Started again at 25 minutes past 11. Engine made 19 strokes per minute. All the 12 pair only ground in 1 hour 11 bushels! but, thinking this to be a mistake, tried another trough, and found it to be 9 bushels per hour, or 108 bushels per hour for the 12 pair, or 1080 bushels in 10 hours. Stopped the engine at 3 P. M. and put on leathers.

Royal Victualling-yard, Deptford.

Two engines of 40-horse power, diameter of stones 4 feet, make 123 revolutions per minute. At Deptford.

Manufac-
tures.

Eight pairs of stones produced in 9 hours, from 38 quarters of wheat weighing 60 pounds to the bushel, 70 sacks of fine flour and 3 of biscuit meal, each sack weighing 283 pounds.

Prepara-
tion of the
corn.

(491.) *Preparation of the corn for grinding.*—In the most improved mills, the corn, previously to being passed through the stones, is cleaned of the dust and other refuse which is found more or less combined with it. In the mill above described, the means employed consist in passing the corn through a cylindrical sieve, which is partitioned inside so as to resemble an Archimedes' screw, by means of which the corn is made to pass over a great surface of wire before it arrives at the extremity, and the greater portion of the dust and other extraneous matter are thereby separated from it. It is then received into a hopper which conveys it to the millstones.

Sometimes mills are constructed, termed *sheeling* mills, whose only purpose is that of preparing corn for the flour-mill; the cleansing is in these mills produced by two or three processes. The corn is received from the hopper upon an inclined sieve, to which is given a reciprocating motion from the Machinery; this serves to deprive it of the sand and small seed which falls through the wires of the sieve during its passage down. It is then passed through a pair of millstones, by the circular motion of which it is sheeled, or a great part of the refuse is rubbed off the grain. The stones of these mills are not cut into channels as in flour-mills, and they are kept at such a distance that the grains are not cut or broken, but merely deprived of the refuse that may adhere to the surface. From the stones it is received into another inclined sieve, where the heavier parts of the refuse fall from it, and thence into a box or hopper containing fanners, which separate the remaining lighter portions. It is then in a proper state for the flour-mill.

Millstones

(492.) *Millstones.*—The description of stone most commonly used in grinding wheat is imported from France, and is usually known by the term French burrs: it is a porous silicious mineral, and so very hard, that a pair of millstones of this material will last for twenty or thirty years at full work before they are worn out. For grinding barley, oats, and rye, a species of stone from the Peak of Derbyshire is often used; it can be obtained for about one quarter the price of the French burrs, but is so much inferior to it in hardness, that it wears out in much less time, and requires repeatedly to be dressed, which is a troublesome operation, and attended with considerable loss of time. It is, however, very common in wind-mills to have one pair of French stones, which are used for wheat, and one of the Peak stone, which are used for oats or rye, or any other description of grinding that may be required.

(493.) In the year 1800, in consequence of the difficulty of obtaining French burrs during the war with France, the Society for the Encouragement of Arts, &c. offered a premium of a gold medal, or one hundred pounds, for the discovery of a quarry producing stones similar to the French burrs; and adjudged it at the next sessions to Mr. Richard Bowes of Conway in North Wales, who discovered a stone of this description in a quarry situated in the Corporation Liberties of Conway. The vein was about eight feet wide, composed of a mixture of quartz and cherts, which by exposure to the air became very hard. Several stones of this description were manufactured and worked in several parts of the Kingdom, and appear, from the evidence given to the Society, to have answered the purpose very well: they are, however,

VOL. VII.

evidently inferior to the French burrs, and they have not been brought into general use.

Machinery

A stone for this purpose was also discovered by Mr. James Brownhill, in the great basaltic rock of the Alley Craig, near Stirling, who examined the texture of several masses of the stone, and found a species which appeared fit for the grinding of wheat; a sample of which was built into a pair of stones under his direction by Mr. Alexander Ball, agent to the Alloa mills, in the same manner as the French burr, and gave such satisfaction to the customers of the mills, as to induce the Alloa mill company to have another pair built, and totally to lay aside the French burr millstones. The uniform texture of this species of stone gives it an advantage over the French, which is at times so excessively porous as to make it necessary to fill up the cavities with a preparation of alum, an operation attended with some expense; but it is, as well as the stone before described, so inferior to it in hardness, that in cases where great velocity of rotation is required, as in steam-mills, the great wear and constant repair attending it cause it to be but little adopted.

All the millstones which are found preserved from ancient times are small, and very different from those in use in the present day. Thoresby mentions two or three such found in England among other Roman antiquities, which were but twenty inches broad; and several others we have described in the Historical sketch preceding the present section. The runner or loose millstone in this sort of grinding was usually very heavy for its size, being as thick as broad, and is the same which is expressly prohibited in Scripture to be taken in pledge, as, lying loose, it was more easily removed. The Talmudists have a story that the Chaldeans made the young men of the captivity carry millstones with them to Babylon, where there seems to have been a scarcity of such stones at that time; and hence probably their Paraphrase renders the text, "have borne the mills or millstones," which might thus be true in a literal sense. They have also a proverbial expression of a man with a millstone about his neck, which is used to express a man under the severest weight of affliction. This also must plainly refer to this small sort of stones.

(494.) *Construction of millstones.*—Millstones are generally composed of a number of pieces attached together by a strong cement, and further secured by iron hoops passing round the circumference. The French stones are always made in a number of pieces in consequence of the difficulty of obtaining large masses of sufficient hardness for the purpose. The cement made use of is however of so hard a nature, that with the assistance of the iron hoops they are rendered as secure, and even more secure, than any other kind of stones.

Construc-
tion of
millstones.

In order to cut and grind the corn, both the upper and lower millstones have grooves or channels, *a a a*, &c., fig. 1 and 2, plate xxxix., cut obliquely from the circumference, to about an inch or an inch and a half from the centres, with others parallel to them, which terminate in a line of a radius to the centre. The number of channels is varied by different millers: in the one exhibited in the drawing there are eight master or long channels, or, the stone is said to be divided into eight quarters, and each quarter has four smaller channels. Sometimes, however, the stones are divided into twelve, and even more quarters, in which case there are usually not above two or three besides the master channel in each quarter. The furrows are cut

Pl. xxxix.
Fig. 1, 2.

Manufac-
tures.

perpendicularly on one side, and obliquely on the other, into the stone, which gives each furrow a sharp edge; and being cut the same on both stones as they lie on their backs, when the upper stone is reversed in its place and in motion, these sharp edges meet each other, and, as before described, cut the corn after the manner of a pair of scissors, which makes it grind the easier when it falls upon the places between the furrows.

It is necessary here to observe that when the furrows are worn shallow, and new dressed with the chisel, the same quantity of stone must be taken from every part of the grinding surface, that it may have the same convexity or concavity as before. As the upper millstone should always have the same weight when its velocity remains unchanged, it will be necessary to add to it as much weight as it has lost in dressing. This is usually done by covering its top with a layer of plaster of Paris, of the same diameter as the layer of stone taken from its grinding surface; and as much thicker than the layer, as the specific gravity of the stone exceeds that of the plaster.

Fig. 2.

Fig. 2 is a view of the lower stone for water or steam flour-mills, which has a wooden bush generally fixed into a hole in the middle of it. Into this a steel pivot is fixed upon which the upper millstone revolves; but in wind-mills, where it is necessary to be continually changing the distance of the stones from the variability of the velocity of the wind, the shaft or spindle of the upper stone passes through a hole in the lower one, and has a bearing in a beam which is acted upon by a governor, so that when the velocity increases, the balls fly open, and, by the action of the levers, lower the upper stone; otherwise, if the stones were at the same distance when going at a great velocity as when going slow, the corn would be driven through the mill without being sufficiently ground. In fig. 1, which is a representation of the under side of the upper millstone, *b b* are two sockets which fit upon the arms of a cross attached to the lower extremity of the shaft, so that the millstone is suspended and takes a horizontal position when put in motion, by reason of the centrifugal force.

Bedding
the stones.

(495.) *Bedding of millstones.*—This requires particular attention, as it is requisite they should be kept perfectly level and firm in their bearing, in order to obtain a good quality of flour. They are usually supported upon cross timbers in the flooring of the mill, and adjusted horizontally by means of wedges: of late years, however, cast iron has been used for the framework of the bedding, and the adjustment made by screws, which is found more convenient, as the wedges are often displaced and troublesome to adjust. In the year 1821, the Society for the Encouragement of Arts, &c. rewarded Mr. T. Austen for a method of supporting and adjusting the bed-stone of a corn-mill, which consisted of fixing the stone in a cast iron frame bedded in plaster of Paris, and of one uniform strength. This frame is bedded on another cast iron frame attached firmly by bolts and nuts to the timbers of the mill. This latter frame had three screws in the bottom part placed on the plan of a triangle, and four screws in the sides, by means of which it could be adjusted either vertically or horizontally with great facility. Fig. 3 is a section through the millstones and floor: *a* the bed-stone which is fixed in the iron case *a' a'*; *c c* the adjusting screws on the points of which the stone rests; *d d* screws to adjust sideways; *e e* two beams of the floor on which the cast iron bed rests, the ribs *b b* of the ends being let in level

Fig. 3.

with the surface; *h h* is a flat circle of wood to cover the adjusting screws and bed which is fastened down by the bolts *i i*; *k k* is a case which incloses the stones to prevent the escape of any flour; *n* is an iron cross, termed the damsel, which, in revolving, strikes the shoe *m*, and gives it a motion which causes the corn to pass down, and affords a supply to the millstones in proportion to the velocity of motion; *p* is the vertical shaft which gives motion to the upper millstone *o*, by means of the cross *q*, which is attached to the stone and fits into the upper part of it.

The mechanism of this part will be better understood by inspecting fig. 4, which is an enlarged view of the upper part of the axle *p*. It is made octagonal to fit the octagonal hole of the iron box *s* to the pin *t* upon which the upper stone *o* hangs. Fig. 5 is a side view, and fig. 6 a plan of the iron bar which is fixed in the upper stone; *l l* are cross arms which drop into the cross of the box *s* and keep the stone in its right position while it is suspended on the pin *t*, these cross arms are shaped like an arch, as shown in the figure.

(496.) *Velocity of millstones.*—The great heat which is generated by the too rapid motion of millstones renders the meal of an inferior quality; at the same time it is desirable to obtain as great a velocity as possible in order to produce the greatest effect. The velocity given to millstones should depend upon their diameter and degree of convexity: for, as the centrifugal force, which gives the tendency of the corn and meal to pass out of the mill from the centre to the circumference, is as the square, while the quantity of grinding surface is simply as the velocity, it is necessary, if the velocity be increased, that the convexity or fall be diminished in order to prevent the corn from passing out of the mill not sufficiently ground. Of late years the millstones made use of have generally been smaller and made to go at a greater velocity than formerly. In the mill lately erected in his Majesty's Victualling-yard at Deptford, upon the most improved construction for the purpose of grinding wheat for the manufacture of biscuits for the Navy, the millstones are rather less than four feet in diameter, and make 120 turns in a minute, and have been found to answer perfectly well. Mr. Fabre observes, that the flour is the best possible when a millstone five feet diameter makes from 48 to 61 revolutions in a minute. Mr. Ferguson allows 60 turns to a millstone of six feet diameter, and Mr. Janson 120 to a millstone of four feet six inches: so that great uncertainty seems to exist about the best size and velocity of millstones. Those most usually adopted in the best water-mills of this Country are from four feet six inches to five feet in diameter, and they make from 80 to 100 revolutions per minute; which agrees with the observations of Mr. Fenwick, an excellent practical mechanic of Newcastle, who states that, with these dimensions and velocity, he has always found the best effect.

(497.) *Dressing the flour.*—The separation of the fine and coarse parts of the flour for the different purposes to which it is applied is effected by two Machines of different construction, termed the *Bolting-mill*, and *Dressing Machine*.

The bolting-mill consists of a reel fitted to an axle which revolves with great rapidity; the reel is covered with a cloth composed of a material termed duck, in the inside of which the flour to be prepared is placed. In the box which contains the reel are placed a number of bars of wood, termed beaters, against which the

Bolting-
mill.

Manufac-
tures.

cloth strikes with considerable violence, and causes the finer portions of the flour to be driven through, and thus separates them from the coarser flour and pollard. The reel is generally composed of six bars of wood united by arms passing through the axle, forming, when so combined, a circle whose diameter is generally $22\frac{1}{2}$ inches at the upper end or head, and tapered to $20\frac{1}{2}$ inches at the tail or lower end; but in some mills they are of the same diameter throughout, in which case they are called equal reels, to distinguish them from the taper ones. The bolting-cloth is a cylindrical sieve, and considerably larger in diameter than the reel upon which it is fixed. At each end of the bolting-cloth a strip or band of leather is fastened to it by being neatly sewed, which serves to strengthen the cloth. The leather fixed to the head or upper end of the cloth has a drawing string inserted in it for the purpose of fixing it over the pin at the head of the reel; and at the bottom of the bolting-cloth six hoops are attached to the tail leather, each of which being brought to the end of a bar, drops into a notch made to receive it, and so fixes the cloth at the tail of the reel.

The reel is placed in an inclined position, and the beaters are placed parallel to the bars of the reel at equal distances around, and about half an inch distant from the bars of the reel when they stand opposite each other. The reel when set to work is turned with such velocity that the centrifugal force would throw out the bolting-cloth to its full extent were it not intercepted by the beaters, so that whilst a constant stream of meal is entering the bolting-cloth at the upper end, the continual and repeated blows of the cloth against the beater force the flour through the meshes of the cloth, which, without the action of the beaters, would soon be clogged or choked up. The offal, consisting of bran, pollard, and sharps, are, by the inclination of the reel, delivered at the tail end of the bolting-cloth.

The complete success of the operation depends very much upon the rapid and powerful vibration of the bolting-cloth, and the equable manner of its action upon the beaters. Both of these requisites, by the common mode above described, of fastening the hoops to the bars of the reel, are very imperfectly arrived at, the only vibration being obtained from the elasticity of the cloth, while, from the stretching of the leather at the head and tail, and the hoops, with various other causes, the cloth frequently takes an eccentric position upon the reel, performs its work but slowly and imperfectly, and when going at a great velocity, or not regularly supplied with meal, is sure to be partially injured or torn to pieces.

To obviate these inconveniences, Mr Jam Ayton, of Trowse, in the County of Norfolk, took out a patent for an instrument or spring to be applied to bolting-mills, for the purpose of facilitating and improving the dressing of flour, and other substances, of which a drawing is given in plate xxxix. Fig. 7, 8 are representations of the instrument prepared to be fastened by two screws to the iron axle of the bolting Machine. A is a cylindrical ring of iron, into which are rivetted the six elastic arms or springs *a b c d e f*. The extreme end of each arm is formed into a broad hook, to receive a loop fixed to the tail leather of the bolting-cloth. These hooks are neatly rounded and made very smooth to prevent the loops being injured when the spring is in action. B is a centre ring, which is also cylindrical; it receives the ends of two conical pointed screws *g* and *h*,

which are secured in the outer ring A, and in this way form two centres of a universal joint; *i* and *k* are two conical pointed screws secured in the centre ring B, which enter conical holes in the centre socket *c*, exactly at right angles with the screws *g* and *h*. The socket C is made with a square aperture in its centre to fit upon the square iron axle of a bolting reel, where it is made fast by the fixing screws. When this instrument is fixed upon the proper part of the axis of a bolting reel, and the loops at the tail leather of the bolting-cloth are placed in the hooks, at the extremity of the arms or springs, instead of being drawn into the notches at the ends of the bars of the reel, a very constant and uniform tension is kept upon the bolting-cloth, so that when set to work, each part of it will strike the beaters with equal force; it preserves a proper degree of vibration, and thereby causes the mill to perform its work in a more regular and perfect manner. Mr. Ayton made several additional improvements in the bolting Machine, in order that his instrument might be used to the best advantage. Fig. 9 represents a side elevation of a bolting Machine on his construction, the inclosing doors being removed in order that the internal parts may more easily be seen. A A A A represent the bars of the frame upon which the bolting Machinery is placed. B B is a wrought iron axis, upon which the mace C or socket is fixed by a screw; *a a*, &c. are six semicircular arms of iron, only four of which are seen in the figure. These arms are fixed to and support a wooden cylindrical rim, and thereby form a frame to fix a net upon, and when the meal enters in a stream, it has the effect of spreading or dispersing it equally over the upper and internal surface of the bolting-cloth; *b b* are two arms of iron fixed also to the mace C; two similar ones are fixed in the same mace at right angles. D represents another mace fixed on the same axis, having four bars or arms *c c c c* similarly placed and fixed in it; *d d* represent two pieces of duck five or six inches wide, fixed at each end to the arms or rods *b b* and *c c*. Two similar pieces of duck are fixed to the other arms, the edge of one being seen at *e e*. Each of these pieces is made to extend about an inch beyond the end of the arm, and the whole constitutes a winnow, over which the bolting-cloth is drawn, and being made fast to the rim D by the running string before named, and the loops fixed to the tail leather placed in the hooks of the patent spring, the most perfect and equable tension will be produced upon the bolting-cloth.

In using the bolting Machine, it is sometimes necessary to adjust the beaters either nearer to the bolting-cloth or further distant from it as occasion may require. The manner in which this is effected in Mr. Ayton's bolting-mill will be seen in fig. 10, which represents an end view of the Machine, corresponding with the elevation. E E is a cast iron plate or ring, let into a recess formed in the tail board where it is confined by the brackets *f f f f*, in such a manner as to be at liberty to move or turn concentric with the axle B of the reel. Another plate or ring, exactly similar in every particular, is let into a recess in the head board. These plates have in each of them six grooves, (as shown at *g g g*, &c. in the figure) equally distant from each other, made eccentric with the ring; and on the edge or periphery of the ring or plate, a few teeth or cogs are formed which engage a pinion H fixed on the spindle I. A similar pinion is fixed on or near the other end of the spindle which engages teeth on the cast iron plate let

Machinery.

Fig. 9.

Fig. 10.

Fig. 7, 8.

Manufac-
tures.

into the head board, and when the spindle is turned either way, both the plates move simultaneously; six radial grooves or slits are made in the tail board, and six similar grooves are made exactly opposite those in the head board; *iii*, &c. represent six cylindrical bolts with pentagonal heads, the other ends of which are screwed into the extremity of each beater, the bolts being previously passed through the eccentric grooves of the circular plates and radial slits or grooves in the head and tail board.

By this contrivance, the distance of the beaters may very speedily be adjusted, and by the use of a winnow instead of the common reel, the injurious effects of the reel bars upon the cloth are said to be greatly avoided. As the extreme edges of the four pieces of duck pass within about three-fourths of an inch of the beaters there is always a space of eight or ten inches in the centre round the axle, from the inner extreme edges of the winnow; and as this part of the Machinery of a bolting-mill revolves with great rapidity, the pieces of duck set the air in very brisk motion, which tends very powerfully to force the flour through the meshes or interstices of the bolting-cloth, while the spring keeps the cloth in a constant state of tension and tremulous motion, thereby preventing any tendency which the flour may have to clog, to fill up the interstices of the cloth.

By this improved bolting-mill, it is stated that four sacks of flour may be dressed in one hour, whereas, by the common one, two and a half or three sacks per hour is considered the average work.

Dressing
Machines.
Pl. xxxix.
Fig. 11.

(498.) *Dressing Machine*.—A Machine of this description is represented in fig. 11: it consists of a hollow cylinder or frame A B covered with wire cloth of different degrees of fineness, the finest being at the end A which is the most elevated, the axle of the cylinder being inclined in the same manner as that of the bolting-mill. Within the cylinder, which is stationary, a reel is placed with its axle exactly in the centre of the cylinder, and to the rails of this reel are attached hair brushes, which, as they revolve, brush against the interior wire surface of the cylinder. The Machine is provided with a shoe or jigger, very similar to that of the millstones, to cause a regular supply of flour or meal through a spout S from the floor above, to which it is elevated by the sack tackle after being ground. The meal, being by this means gradually fed into the cylinder, is, by the motion of the brushes of the reel, sifted or rubbed through the wire. The finest of the flour will of course go through at the upper end, but no other kind, the second through the next division, and so on till the bran falls out through the end of the cylinder, being too coarse to go through any of the wires. The cylinder is inclosed in a tight and close box to prevent waste by the flour flying about, which box is divided into a number of partitions, to collect the flour of different degrees of fineness. The number of partitions and their position are varied by different millers; the general number is however four, and the flour which they receive is termed, first, second, third, and pollard. The wire cloth is manufactured in lengths of 4 feet and $9\frac{1}{2}$ inches in breadth; the length of the cloth covers the circumference of the cylinder, and is fastened down by the wooden ribs *iii*, &c. three of which are situated in $9\frac{1}{2}$ inches, or the breadth of one piece of cloth. The degree of fineness with which the cloth is manufactured is with 64, 60, 38, and 16

Machinery.
meshes to the inch, the arrangement of which is commonly as follows. The first length is of 60 meshes to the inch, being a slight degree coarser than the next, which has 64. This arrangement is found desirable, because when the meal first enters the cylinder it is still moist and warm from the stones and is liable to clog the fine wires; moreover, at this part of the cylinder, the brushes have scarcely acquired their full action, so that, although the wire is coarser, a finer sort and less quantity of flour passes through than in the second length. The first partition is generally placed at the end of the second length of cloth, forming a division to receive the finest description of flour, termed *firsts*. The next length on the cylinder is of cloth of 64 meshes to the inch, which, although of a greater degree of fineness than the last, receives through it flour of an inferior quality, termed *seconds*, which is collected into the second division of the Machine; sometimes an additional length of wire is added to this division of 56 meshes to the inch; the next length is 32 meshes to the inch, and the last 16: the product of these last is collected separately, and forms the thirds flour and pollard. The bran, which is composed of the husks of the corn, and which is too large to pass through any of the wires, passes out at the end of the Machine. The divisions of the case or box are not confined in their position, so that the miller, by shifting them, can obtain flour of any degree of fineness to suit the taste of his customers. The pinion for turning the dressing Machine is generally made so as to turn either way, the object of which is, that when the Machine has been running for some time in one direction and the brushes become bent on one side, the motion may be reversed to give them an equal wear on the opposite side.

In consequence of a liability of the meshes of the wire to become clogged, a patent was taken out by Mr. John Smith of Bradford, in Yorkshire, for the use of a brush to be applied to the exterior of the cylinder. It is of a circular shape, and made free to revolve upon a spindle attached to a projected part of the box or frame containing the Machine. The cylinder is made to revolve by the Machinery which causes a revolution of the brush, and consequently the hairs to penetrate the meshes of the wire cloth.

Mr. Smith also introduced the use of cast iron instead of wood in the construction of the ribs of the cylinder, which is certainly a considerable improvement, as it admits of a much readier method of fixing the wirework.

The dressing Machine is of more recent invention than the bolting-mill, and is now more commonly employed than the latter, although, in all large mills, both Machines are employed. The bolting-mill only produces two descriptions of meal, *viz.* flour and pollard or bran, so that, before the use of the dressing Machine, it was necessary to have several of them, with cloth of different degrees of fineness. They are generally employed when the stones are first dressed; the pollard which comes from the dressing Machine having then a good deal of flour mixed with it, which is very readily separated by the bolting-mill: in such cases it is very common to grind the pollard a second time with a pair of dull stones which have become unfit for grinding corn without dressing them again. The meal being then dressed in the bolting-mill, produces a considerable quantity of seconds flour.

(499.) *An Account of the Quantities of all Sorts of Grain, Meal, and Flour, stated in Quarters, which were imported into Great Britain from Ireland, from the Islands of Man, Guernsey, Jersey, Alderney, and Sark, and from Foreign Parts, in each Year, from 1820 to 1831, both inclusive.*

Various kinds of corn-mills.

(500.) *Mills for bruising grain, malt, &c.*—The mill described in the preceding section, is one of the most complete in England and of course in Europe, and from this to the small hand-mill there are necessarily many gradations; there are also gradations in the operations of grinding. In the mill we have described, the corn is reduced to its ultimate state of fineness; but such means of perfect grinding are not necessary in all cases, such as in the preparation of barley for making pearl barley, for breaking or grinding peas, beans, &c. for cattle, bruising malt for brewing, &c. But as the processes in all these cases differ rather in degree than in principle, it will not be expected that we should enter into a minute description of these kinds of mills, which would occupy our pages and our plates with little interest to the reader; in general the principle is the same, and it will readily be comprehended that as less accuracy of grinding is requisite, so some of the means employed in the more perfect mills may be omitted, and the process rendered thereby so much more simple, cheap, and expeditious. It will perhaps only be necessary to observe that the malt-mill is not always of the grinding kind, the malt being merely made to pass between two rollers to bruise it. It is, however, frequently preferred in a ground state, and then of course the grinding process must be had recourse to.

Fulling-mill.

(501.) *Fulling-mills.*—The fulling-mill in manufactures is a Machine employed for washing, scouring, or fulling cloth or other material, with a view not only of cleansing it, but also of rendering it thicker and more repellent of rain, &c. The practice of fulling cloth is of considerable antiquity. Pliny states that one Nicus, the son of Hermias, was the first inventor of the art of fulling, who was a Governor in Greece in the time of the

Romans; it is therefore probable that the fulling-mill, in point of antiquity, stands next after the corn or flour-mill.

The process of fulling consists in constantly agitating and exposing new surfaces of the cloth or material under operation to the action of water or other menstruum with which the goods to be operated upon are constantly supplied. This is performed by two or more beaters or mallets, which are successively raised by the action of a wheel, commonly of a water-mill, and let fall with their weight upon the cloth, which they strike and turn over in the trough in which it is placed, at the same time a stream of water is constantly passing through the trough to carry off the dirt and impurities which are loosened from the cloth by the agitation of the mallets, or, as they are technically termed, the *stocks*.

These stocks are formed after the manner of a mallet, that is to say, with a long wooden beam or handle several feet in length; the head of the stock also resembles the head of the mallet, being likewise a heavy block of wood, but formed to a circular arc behind, corresponding to the circle described from the centre of suspension of the handles and to the circular case or trough in which they work. But the end of the mallet which strikes the cloth is not left flat, but formed into two or three projections like steps, so that on striking the cloth it may double and bend it in various directions. The shaft of the stock projects on one side beyond the head, and a sort of cam wheel fixed on the axis of the wheel shaft as it revolves keeps continually raising the stocks and letting them fall on the cloth, while a pipe is constantly supplying the water which is running off, carrying with it the dirt which has thus been removed. Many of these stocks are ranged in a line, and as

Process of fulling cloth.

Fulling-mill.

Manufac- tures. stated, they may be worked either by a water wheel or steam engine; in the former case the axle of the water wheel is employed to move two or three pair of stocks according to their weight and dimensions, while the others receive their motion from one or more similar shafts turned by cog wheels from the shaft of the water wheel. We have not thought it necessary to give a figure of this mill, which is so very simple in its construction and operation as to be easily comprehended without one.

Fulling with soap.

(502.) In fulling cloth with soap, if it be coloured, a piece of forty or fifty yards is laid in the trough in the usual manner, but without soaking. To full this, about fifteen pounds of soap are required, one half of which is to be dissolved in two pails of river or spring water made as hot as the hand will well bear it. This solution is poured little by little upon the cloth as it is being laid in the trough, and with this it is to be fullled for about two hours, after which it is taken out and stretched. The cloth is then immediately returned to the trough without any fresh soap and then fullled for two hours longer. It is then again taken out and well wrung, to press out as much as possible of the grease and other impurities.

After the second fulling, the remainder of the soap is melted, as the former was, and cast at four different times on the cloth, taking out the same every two hours to be stretched, and to relieve the plaits and wrinkles it has acquired in the operation; when it is perceived to be sufficiently fullled and brought to its proper quality and thickness, it is scoured for the last time in hot water, keeping it in the trough till it is quite clean.

As white cloths full more easily than coloured cloths, they require less time, and do not require generally more than two-thirds the quantity of soap.

Fulling, however, which we have hitherto spoken of as applicable to cloth, is practised, although somewhat differently, on other materials, as stockings, caps, and other woollen goods, as also in the manufacture of hats.

The fulling of stockings and caps is of course done on a smaller scale, and may be effected either with the feet or hands, or on a kind of rack or wooden Machine armed with teeth of the same materials, or with horses' or bullocks' teeth. The ingredients made use of are urine, green soap, white soap, and fullers' earth, but water softened with chalk is said to be preferable. Woven stockings are fullled with soap alone, and knit ones with the ingredients above mentioned.

Fulling the felt of hats.

(503.) The fulling of the felting in hat-making, has for its object the intimate connection of the fibres, and a more perfect and durable cohesion of the whole mass. For this purpose the mere mechanical act of pressure is insufficient. Experience has long shown that in this process it is necessary to make use of a bath of water heated nearly to boiling, into which are put from ten to fifteen pounds of lees of wine for each hundred pounds of water, and the heat should be kept up during the whole time of working, and every three or four hours a fresh supply of lees is added. Into this bath the workman plunges his felt and begins the second process. The felt is dipped in, and immediately again taken out and squeezed, bended and rolled, by pressure, in different directions, sometimes with the hand defended with leather, and sometimes by means of a roller or other similar instrument. The immersion and working of the felt are repeated and continued till the stuff is well condensed and has acquired the required solidity.

The operation of fulling is employed to form a dense

and compact stuff with the fibres of hair, and to determine the intimate cohesion of its component parts; and since the mere mechanical operation is not sufficient for this purpose, even with the assistance of a water bath at the boiling heat, without the addition of lees as a necessary condition, this last must be considered as a chemical solvent, which acts directly on the substance of the hairs themselves, and produces, either by softening or swelling them, an alteration necessary to insure the cohesion of the different fibres of the stuff. But the lees being composed of the mucilaginous and colouring parts, which are separated, together with a great quantity of tartar, or the acidulous tartrate of potash, it became necessary to ascertain, in a positive manner, what might be the principle of its action. The Editor of the *Encyclopédie Méthodique* affirms without hesitation, that it is the alkali or potash of the lees which determines the fulling. "But in order to show (says Mr. Colmet) how erroneous this opinion is, nothing more is necessary than to dip a piece of blue paper into the bath, by which the former becomes instantly red; and if, after several hours' work the state of the bath be again examined, it is found that the acidulous tartrate of potash is partly exhausted, and the workmen soon perceive, from the difficulty of continuing their work, that a new quantity is required to be added. And again, if we consider the sparing solubility of the acidulous tartrate of potash in cold water, it is easily seen why in this process the water must be kept nearly boiling. Whence it is evident that it must act by the portion of acidate which it contains." Hence our author was induced to think, that the sulphuric acid might be advantageously substituted in the place of the lees; and as 12 pounds of lees are usually added to 100 of water, he estimated by approximation that one gross of sulphuric acid would be equivalent to at least one pound of the lees, and consequently that 12 gross of sulphuric acid would be sufficient for 100 pounds of water. His conjectures were soon confirmed by experiment, and after a fair trial it was ascertained that the use of the sulphuric acid is much preferable to that of wine lees; that it is not only much more economical, but still more convenient in the use; and, what is yet more important, that the health of the workmen is not injured by the excess and duration of the heat, the thick vapours, and the disgusting odour, which exhale from the bath, particularly when the lees have been altered by mouldiness and putrefaction, which is very common in these manufactories. When the sulphuric acid is employed, it is useless to keep the bath nearly boiling, as was formerly done. A degree of heat of 25 or 30 degrees (90° or 100° of Fahrenheit) is sufficient for good fulling. The saving of fuel is an object of importance in manufactories, and as very little fire is necessary when sulphuric acid is used, caldrons of lead may be substituted instead of copper boilers, the first cost and annual repair of which are very considerable.

The felts prepared by this new process are also of a very superior quality to those which have been worked in the bath with wine lees. In fact, the mucilaginous and colouring matter of the lees, which are suspended in the bath, penetrate the texture of the stuff, and adhere with more or less force; and when, after having passed the hats through the dye, they are beaten, a fine black dust flies off in great abundance, which not only weakens the texture of the felt, but by diffusing itself through the manufactory greatly incommodes the work-

Machinery.

Manufac-
tures.

men, and frequently occasions coughs and disorders of the throat.

"Hats felted in this manner," says a manufacturer who had adopted this process, "are not only clear of the powder which abounds in the others, but they take the dye better and are cleaner."

Oil-mills.

Oil-mills.

First pro-
cess de-
scribed.

(504.) The term oil-mill is applied to mills for expressing the oil from fruits or grains. In England they are generally made use of for the manufacture of oil from linseed and rapeseed, which are the produce of almost every County. A great number of oil-mills are to be met with in Hull and other parts of Yorkshire, as well as in some other Counties. The process employed by the most careful manufacturers consists in first passing the seed between iron rollers, in order to crack all the grains without separating their parts, after which they are made to pass under two vertical mill-stones, which revolve upon a horizontal bed, where the seeds are further bruised, and are prepared for the process of compression. The use of the iron rollers, however, is not general; in many of the Dutch mills the revolving stones, or *runners*, as they are usually termed, are alone made use of: the rollers are, however, considered, where they have been employed, greatly to facilitate the operation of grinding; for the grains are so hard and smooth that without them they slip away from beneath the running stones, and require much longer time to be crushed than when they are previously broken by the rollers; but these, on the other hand, require so much power that, in small mills, they cannot be worked with the other Machines at the same time. This, however, is little objection to them, for they act with so great rapidity as in a very short time to prepare seed enough for the whole day's work.

Second pro-
cess.

The seed having passed under the running stones until it is sufficiently bruised, is collected in hair bags, and placed in the press, where the oil is extracted by the compressive force of wedges. In olive-oil-mills this process is generally performed by a screw press; but the grains of lint and rapeseed are so excessively hard and smooth on their surfaces, and the fragments of their shells, however broken, form so many little concavities which retain the oil, that a much greater force is necessary than can be obtained by this means. The method of effecting this enormous pressure is by wedges, which are driven into a strong timber framing, containing the seeds as they come from the running stones, previously placed in hair bags for the purpose, as above stated. The wedges are driven by the blows of a heavy pestle, which is raised by the Machinery, and the operation is continued until the wedges are so tight that the pestle rebounds from them three times, when they are judged to be sufficiently driven. The oil thus obtained is considered of the best quality, and is kept apart in a large cistern, which is divided into separate portions by partitions for the different qualities of oil.

The oil cakes of this pressing are taken out of the bags, broken to pieces, and put into the mortars for the first stamping. There the paste is again broken down, and the parenchyma of the seed reduced to a fine meal; thus free egress is allowed to the oil from every vesicle in which it is contained, but it is now rendered much more clammy by the forcible mixture of the mucilage, and even of the finer parts of the meal. When suffi-

ciently pounded, the workman stops the pestle of a mortar when at the top of its lift, and carries the seed to the first chauffer pan, where it is heated to about the temperature of melting bees-wax, (this we are told is the test,) and all the while stirred up by an instrument termed the spatula, which is usually put in motion by the Machinery. After this operation, it is again put into the hair bags, in the manner already described, and the oil which drops from it during this operation is considered the best of the second quality, and in some mills is kept apart. The paste is now subjected to a second pressing, and the oil obtained is that of the ordinary second quality. All this operation of pounding and heating is performed by one workman, who has constant employment by taking the four mortars in succession. The putting the paste into the bags, and conducting the pressing, give equal employment to another workman.

In the mills of Picardy, Alsace, and most parts of Flanders, the operation ends here, the produce of the chauffer being often increased by putting a spoonful or two of water into the pan among the paste. The Dutch, however, take more pains; they add no water to the paste of their first stamping, which they say greatly lowers the quality of the oil. The cakes which result from this pressing, and which are sold as food for cattle, are still fat and soft, and the Dutch very commonly break them down and subject them to the pestles for a second stamping. This reduces them to an impalpable paste, stiff, like clay, which is lifted out and put into the second chauffer pan: a few spoonfuls of water are then added, and the whole is kept for some time at the heat of boiling water, and carefully stirred during the time. Thence it is shifted into the hair bags of the last press, subjected to the greatest pressure, and a quantity of oil of the lowest quality is obtained, sufficient to give a satisfactory profit to the miller. The cake is now perfectly dry and hard, like a piece of board; it is, however, useful to the farmers to whom it is sold.

In this way there is a great quantity of oil obtained which would otherwise be lost, and there are small mills in Holland which have no other employment than extracting oil from the cakes which they purchase from the French and Brabanters, after passing the process of their mills: a clear indication of the superiority of the Dutch practice.

Fig. 1, pl. xl. is a representation of an oil-mill employed for grinding and pressing linseed, rapeseed, and other oleaginous grains. A is a spur wheel, which is put in motion by a water wheel, a steam engine, or any other motive power: it has fifty-two teeth, and engages the wheel B of seventy-eight teeth, which is attached and gives motion to the horizontal shaft C C, termed the tumbling shaft. This shaft is furnished round its circumference with wipers for lifting the pestles, so that each may fall twice during one revolution of the shaft: these wipers, since iron shafts have been introduced, are also generally made of iron. They consist of a square socket, which is fitted on the shaft with arms, having rollers at their extremities, which are found to be a very great improvement, because they not only diminish the friction, but also the wear, which naturally takes place on surfaces rubbing upon each other.

DDDD is the framework which supports the pestles. It consists of four strong uprights, with cross timbers or rails bolted firmly to them. These cross timbers, with small transverse pieces fixed between them, serve

Machinery.

Oil-mill, de-
scription of.
Pl. xl.
Fig. 1

Manufactures.

as guides for the perpendicular motion of the pestles. When the pestles are not required to work they are raised up, so that the lifts are clear of the wipers, by means of levers *a a a*, and these engage the part marked *d*, which is the projection on the side of the lifter. These levers turn upon a joint at *c*, so that by releasing the rope *d d* they will assume a perpendicular position, and the pestle will be left free to work.

I I is a strong block of stone or timber, which contains the press boxes *P P'*, where the grain is squeezed after it has come from the running stones and the six mortars *L L*, &c. where the cakes are put in for stamping, and which are generally hollowed out of the block itself. A board is commonly placed on each side of these mortars standing on its edge and inclined a little backwards; this forms a sort of trough which prevents the seed from being scattered about by the fall of the pestles. The large press box *P*, where the grain is squeezed, immediately it comes from the stones, is also very commonly hollowed out of the block; at all events if it is framed together, the utmost attention must be paid to give it sufficient strength, as the lateral pressure produced by the wedges is enormous. The second press box *M* for squeezing the grain after it has passed under the pestles is generally smaller and not required to be so strong.

The bags of seed *f f* are included between two iron plates united together at bottom in the manner of book lids, the bag is shut up between them, and there are small holes in the bottom of the press at which the oil oozes out into vessels placed to receive it: *w w* are the driving wedges, and *h h* the dischargers or inverted wedges by which the pressure is relieved; the remaining part of the press is filled up by blocks of wood, which rest firmly upon the bottom to prevent their being carried down by the wedges, having thin pieces of wood between them and the wedges to make them slide easier by each other. *R R* are the drivers which strike the wedges that press the oil, and *S S* are the stampers which strike the dischargers or relieving wedges: these are each put in motion by wipers upon the horizontal shaft, in the same manner as the pestles of the mortars: the action of this part will be better understood by inspecting the side elevation of the pestle frame.

In this figure (2) *A* is the section of the tumbling shaft with the two wipers attached to it, which engage the lift or projecting piece *b b* upon the pestle, and raise it for a considerable distance, until it is naturally relieved during the revolution, when the pestle falls with its whole weight in the mortar; it is then again raised by the next wiper, whereby a constant succession of blows is kept up.

Chauffer pan.

(505.) The chauffer pan is seen at *o* in fig. 2; it consists of a small circular copper pan, which is heated by a furnace underneath. *k* is the spatula which is attached to the lower end of a vertical spindle, and which by turning round among the grain in the chauffer prevents it from sticking to the bottom and sides and getting too much heat. In some modern mills the chauffer pan is heated by steam from a boiler, which is much to be preferred, as sufficient heat is thereby obtained for the purpose without any danger of burning the grain, which is liable to happen in a furnace heated by charcoal. The spindle to which the spatula is fixed, is put in motion by a system of wheelwork. In the mill in question, a wheel of twenty-eight teeth upon the main shaft, gives motion to another of twenty teeth upon a

small horizontal axle or shaft; this axle has another Machinery wheel upon it at its other extremity, which engages a wheel upon the spindle of the spatula, and thereby gives a rotary motion of a little less velocity than the main shaft.

l is a lever, one end of which is attached to the pillar *p*, and serves to raise the vertical spindle out of gear when required; it has a hole at *m* through which the spindle passes, and this spindle has in that part a shoulder which rests on the border of the hole, so that by the motion of the lever the spindle may be disengaged from the wheelwork at pleasure. Motion is given to the lever by means of a rope attached to the end, which hangs down by the side of the chauffer pan, so that the man engaged there can very readily raise the spindle out of gear.

In front of the chauffer pan is a basket which tapers downwards and opens below in a narrow slit. The hair bags in which the grain is to be pressed after it has been warmed in the chauffer, are filled by placing them in this basket. The grain is lifted out of the chauffer by a ladle, and put into these bags, and a certain quantity runs from it through the slit in the bottom, which, as before mentioned, is considered of very good quality.

(506.) *Running stones* are the most important part of Running oil-mills, as upon the action of them materially depends stones. the good quality of the oil. They are made to revolve in a strong framework attached to a vertical axis, which also revolves slowly by a large cog wheel at the upper part, which engages a wheel upon the main horizontal shaft. Thus they have two motions, a rotation round their own axis, and that by which they are carried round upon the nether or lower millstone.

In fig. 1, *N N* is the vertical shaft and the framework which carries the millstones. The horizontal axis *O O* of the running stones passes through the vertical shaft and has its bearing in the ears of the framework. The holes in the millstones are made a little wide, and those in the ears of the frame are made oval in a vertical direction, giving great freedom of motion which is necessary for the runner millstones, because more or less of the grain being below them at a time, they must be at liberty to get over it without straining, which might perhaps break the shaft.

The nether millstone is supported upon a firm foundation of masonry, and has a border or hoop which surrounds it to prevent the escape of the grain by the motion of the stones; it has a piece of wood in the centre which carries a brass bush in which the vertical shaft revolves. In order to collect the grain under the stones, there are two rakes or sweeps, which are attached to the framework and revolve on the surface of the nether stone, in such a manner that the grain which is dispersed in all directions by the pressure of the stone, is collected in a ridge in the line of their motion; the inner rake collects grain under the outer runner and the outer rake under the inner runner. The outer rake is also furnished with a rag of cloth which rubs against the border or hoop that surrounds the nether stone, so as to drag out the few grains that might otherwise remain in the corner, and in this manner the grain is always turned over and crushed in every direction. One of the runners is set about two-thirds of its own thickness nearer the shaft than the other; they have thus different treads, and the grain which is a little heaped towards the centre, is of course crushed by both. The inner rake gathers it up under the outer stone in a ridge shape, and the stone passes

Manufac-
tures.

over it and flattens it, and it is gathered again in a ridge by the outer rake: this consists of two parts; the outer part presses close on the wooden border which surrounds the nether stone and pushes the seed obliquely inwards, while the inner part of the rake gathers up what had spread towards the centre. The other rake has a joint near the middle of its length, by which the outer half of it can be raised from the nether stone, while the inner half continues pressing upon it, and thus scrapes off the moist paste. When the seed is sufficiently bruised, the miller lets down the outer end of the rake; this immediately gathers the whole paste and pushes it obliquely outwards to the wooden rim, where it is at last brought to the part left unboarded, and falls through into troughs placed to receive it. These troughs have holes in the bottom, through which a quantity of oil drops all the time of the operation. This part of the oil is directed into a particular cistern, being considered as the purest of the whole, having been obtained without pressure by the mere breaking of the husk of the seed.

Crushing
rollers.

(507.) In the mill above described, rollers for breaking the grains of the seed previous to its passing under the vertical stones not being made use of, it is necessary to give a separate description of them as they are usually adopted in modern mills. They are generally made of cast iron, and truly turned in a lathe, their spindles running in brass bushes fixed in an iron frame bolted down to the framework of the mill. These frames have mortises in them in which the bushes for the rollers are placed with liberty to slide, and adjustable by screws through the ends of the iron frames; by which means the rollers may be set at any distance apart, according to the size and nature of the seed which is to be crushed between them. The rollers are usually made of different sizes, so that their circumferences have different velocities: this gives them a tendency to draw the seeds in, and enables them to perform their work quicker. One of the rollers has a small spur wheel or pinion on its axis which engages the cog wheel on the main horizontal shaft, so that it makes about seven revolutions to one of the main shaft. It conveys its motion by another pinion to the other roller, so that their surfaces roll upon each other and bruise the seed as it passes between them. The pinions of the rollers are sometimes made to have a different number of teeth in order that the surfaces of the rollers may have a different velocity; but this is not necessary if they are of different diameters.

The seed is put into a hopper, supported at some distance above the rollers, and it runs out at an opening in the bottom into a trough called the shoe, which is continually shaken by a piece of wood nailed to it, which rests upon the cog wheel; and by this means the shoe continually feeds the rollers with a small quantity of seed, without any danger of choking them up. It is proper to have a plate of iron attached to some part of the frame, and kept constantly pressing against the rollers, so as to scrape off the seed which may adhere to them. The seed, after having passed between the rollers, falls upon an inclined board placed in a frame beneath them, and is thus shot down in a heap before them, whence it is conveyed by a labourer to the running stones to be crushed. The latter part of the process is exactly similar to that employed in mills where these rollers are not adopted.

(508.) We have thus far described the common processes employed in the manufacture of oil; in many

parts, however, of Holland and England, considerable variations in the process occur, according to the nature of the grain and the quality of oil that may be required. In some of the Dutch mills, a much greater quantity of oil is produced in the grinding without pressure, by having the bed of masonry which supports the lower millstone formed into a little furnace and gently heated. But the utmost care is necessary to prevent the heat from becoming too considerable, as it causes the oil to dissolve too much of the fermentable substance of the seed, and exposes it to the risk of soon growing very rancid. In general this is thought a hazardous practice, and the oil does not bring so high a price.

The seed in this Country is seldom so ripe as to yield any oil from the running stones without pressure; but some millers take a quantity of their best seed from the stones, and putting it into bags give it a moderate pressure by a screw press. The oil thus obtained, is called cold drawn, and is sold at a higher price for the use of cabinet makers, who rub their ornamental work with it to give it a polish. In other mills the cold drawn oil is nothing more than that first obtained from the press, but without heating the seed.

When the seed is very dry, a little water is thrown among it while grinding, which very much facilitates the process. In about twenty minutes a charge of seed will be sufficiently ground, and it is generally taken to the chauffer pan, and submitted to a gentle heat previous to being pressed: this part of the process is, however, very much varied by different millers, according to the nature and state of the seed, and other circumstances, often depending upon the locality of the mill.

The Dutch have been generally considered to excel in this description of manufacture, and the nicety with which that industrious people conduct the whole business is very remarkable. In the oil cistern, the parenchymous part, which unavoidably gets through in some degree in every operation, gradually subsides, and the liquor in every division consists of oil of different degrees of purity. The pumps which lift it out of each division are in pairs, one takes it up from the very bottom, and the other from half the depth. The last only is barrelled up for the market, and the other is put into a deep and narrow cistern, where the dregs again subside and more oil of that quality is obtained.

The produce of oil from linseed has been found, from an average of four months' work of an oil-mill in Yorkshire, to amount to 5616 gallons of oil, from 280 quarters of linseed, generally weighing 30 stone (of 14 pounds each) per quarter, which is at the rate of $20\frac{2}{3}$ gallons per quarter. The greatest produce in the period from which this average was obtained, was 409 gallons from 20 quarters, or $20\frac{9}{10}$ gallons per quarter. The least produce was $19\frac{1}{2}$ gallons per quarter. The number of presses is of course varied according to the power of the mill, some having as many as 10 or 15 in use. A press will generally press seven hundred weight of seed per day, in the first operation, when the grain comes immediately from the rollers; but only two or two and a half hundred weight per day, in the second pressing, as it requires so much more time for the second operation. The wedge press oil-mill has been in use for many years with but little variation in its construction, and is still preferred by the generality of oil pressers, although within a few years several different modes of expressing oil have been invented.

Press.

ford in Kent, April 1823, a new press for extracting the oil from seed, which consisted in the employment of cams or eccentric rollers, which by the power of a steam engine are turned round so as to press laterally against sliding plates of iron which form the sides of boxes, that contain the bags of seed to be operated upon.

By this improved apparatus, it is stated that a greater quantity of oil may be extracted than by the ordinary mode, and that the oil cakes left in the bags will be much lighter than those usually produced; it appears, however, not to have got into general use.

Hydraulic
oil Press.

(510.) Bramah's Hydrostatic Press has been applied to the extraction of oil from seeds with considerable success. The first mill on this principle was constructed in 1821, at Bremen, for Mr. Henry Plump, who states that he is satisfied that such mills are the best Machines at present employed for the crushing of seed for oil.

Pl. xl.
Fig. 3, &c.

A representation of this mill or press is given in plate xl., where fig. 5 is a front elevation of one of the oil Presses, fig. 3 an elevation of the two injecting pumps with their frame, cistern, &c., and fig. 4 is an enlarged section of the stop and discharge valves by which the necessary connection is made between the pumps and cylinder.

A A A are brackets supporting the two cylinders and affixed to cast iron plates resting upon the brickwork; B B the press cylinders; C C strong wrought iron bars by which the frame containing the oil bags is secured to the press cylinder. D D is the frame or box which contains the seeds, which is constructed of cast iron with circular ribs at the end *a a*, to increase the strength in the direction in which the pressure is exerted; E is the press piston, which is connected by a strong unwrought iron rod with the cast iron plate or follower F F. The followers have each a friction wheel or roller at the under part, which moves upon the false bottoms of the oil boxes, and are drawn back by means of weights attached to chains passing over pulleys, and rising and falling in a pit made in the brickwork to receive them, as shown by dotted lines. The seeds to be pressed are contained in woollen bags, which are unfolded by horse-hair mattresses, enclosed in leather wrappers, as in the ordinary oil-mill, and are placed in the oil boxes, with cast iron plates grooved at their edges between them, as seen in the figure at *b b b*, &c. Each of the plates have handles *c c c*, &c. at the upper extremity, by which they can be readily lifted out of the oil boxes.

The expressed oil makes its escape through perforations in the false bottoms of the boxes, and flows out by short pipes, technically termed *teats*, made in the sides, to reservoirs destined for its reception in any convenient part of the floor or underground premises. The oil which may occasionally exude at top is prevented from running over by the raised border of the box, and is conveyed to the bottom by a groove at the end of each box communicating with the bottom.

The injection pumps are so arranged as to be worked by a rotary motion from a steam engine, or other first mover, communicated by a toothed wheel to the horizontal shaft *d*. Upon this shaft is attached a crank, which can be adjusted to any length according to required circumstances. Upon the neck of the crank is a connecting rod to communicate motion to the beam above, as seen in the figure, and this beam actuates two injection pumps by means of piston rods furnished with

the usual parallel movements, all of which being of Machinery ordinary and of well-known construction, are not detailed in the drawing.

As the construction of the injection pumps will more fully be described under the article Presses, it is necessary here only to mention some additional contrivances which are required to adjust this principle to the present purpose.

One of the injection pumps is required to have its piston four times the area of the other, so that it injects at each stroke four times the quantity of water produced by the smaller pump, and its safety valve is loaded with a weight proportionally smaller, so that its effect upon the seeds is confined to the commencement of the pressing, when the resistance is not so great, for the purpose of expediting the operation. As the resistance of the seeds increases, the power must likewise be increased, and therefore the lesser pump alone is employed to finish the compression; as, however, both pumps are continually worked by the engine, it becomes necessary, in order to avoid a needless expenditure of power, to relieve the larger pump of its labour, or to reduce it merely to that of the friction arising from working the piston in the cylinder, which is effected by raising the lever and weight of its safety valve, by means of a line connected with it, and passing over pulleys so as to bring the handle at its other end conveniently within the reach of the workman; and thus the water from the large injection pump escapes and falls back again into the cistern. The workman is apprized of the proper time for lifting this safety valve by the rushing noise which the water makes in escaping through it: which effect takes place immediately the resistance afforded by the nut bags exceeds the power of the larger pump. The injection pump may be situated at any distance from the Presses, and the water conveyed from them through strong copper pipes placed underground and continued up through the junction part Z to the stop and discharge valves H and I.

A drawing of the right-hand pair of valves upon an enlarged scale, is shown in fig. 4, in which G is the pipe leading from the junction part Z: H the stop valve which opens and shuts the communication from the pumps: I the discharge valve, having a groove or channel round it, to permit the water to stop from the pumps to the press through the curved pipe *j*. When the Press is to be released, it is only necessary to raise the screw valve I, which allows the water to flow out at the waste pipe K, through which it may escape back to the cistern, or be conveyed to a drain or sewer, as circumstances require. One pair of injecting pumps may be employed to work four oil presses with the same facility as two; but in this case two Presses should be in action at once, whilst the others are recharging. In order to allow for a small horizontal movement, which may take place by the alternate expansion and contraction of the wrought iron bars C C, from the strain applied in pressing, and which causes a liability to fracture the copper pipes leading from the stop and discharge valves to the cylinders, it is found necessary to make them of a curved form, as shown in the figure.

The general operation of the mill is as follows: the seed is in the first place bruised or broken between iron rollers, in the same manner as in the common mills, after which it is submitted to the first operation of the Press. The cake is then removed and passed under vertical runners until sufficiently reduced, when it is

Manufactures.

warmed in pans and again submitted to the Press. The first pressing is effected as speedily as possible, generally in about six minutes, but in the second more time is allowed.

There are employed altogether in this mill, which contains two Presses, three men and one boy; one of the men has the charge of warming the seeds in the pans and filling the bags; another takes care of the pressing; the boy takes the cakes out of the bags, trims them, and puts the bags into their proper places; and the other man has the management of grinding the cakes after the first pressing under the vertical runners.

Comparative effect of different presses.

(511.) In the way represented above, there was pressed, in the beginning of the year 1822, from five o'clock in the morning to seven at night, amounting to a day's work of 12 hours, allowing for stoppages, half a Bremen last, or from 2000 to 2020 pounds of seeds; but they afterwards increased the quantity, when better acquainted with the action of the Machine, to $4\frac{3}{4}$ lasts per week, which is equal to from 2667 to 2693 pounds per day. The product of oil got from a last of seed, varied with the quality of the seed from 1300 to 1600 pounds; about 1500 pounds is considered to be the average quantity; of this about 1250 pounds are obtained the first pressing, and 300 pounds the second.

Several comparative trials with the same seeds have been made with Mr. Plump's mill, and a fine Dutch mill worked by Dutchmen at Bremen, and the results have proved in favour of the former.

A comparison was also made between the daily produce of Mr. Plump's Presses, and that performed by stampers at a large mill belonging to Michael Shepley, Esq. at Carshalton in Surrey, where the regular work of three men at the stampers amounts to seven quarters, two bushels of seeds, or 58 bushels per day, and that 47 pounds is the full average weight per bushel of good seed.

Mr. Plump's Presses produced, as before stated, from 2667 to 2693 pounds Bremen weight, or $\frac{2667 + 2693}{2} =$

2680 pounds Bremen on the average. The ratio of the Bremen pound to that of the English is as 100 to 109.8, as appears from Dr. Kelly's *Universal Cambist*, so that

2680 pounds Bremen weight will be $\frac{2680 \times 109.8}{2} =$

2942.64 pounds English. This quantity divided by 47, the average weight in pounds of a bushel of seed, will be 62.6 bushels, from which it appears that the effect of the hydro-mechanical Presses is not inferior to that of the ordinary method by stampers.

The hydrostatic press mills are said to possess these advantages over the ordinary method: that no peculiar locality for the erection is necessary; and that the space required for each Press is much less than that which would be occupied by a sufficient number of stampers to contain a like quantity of seed, particularly as the principle of the communication with the pumps admits of Presses being placed at any distance from, and in any direction to, the position of the first mover, which a peculiarity of situation may demand. The hairs and bags are also found to last much longer than those used in the stamper presses.

Mill for cocoa nut oil.

(512.) These advantages, it appears, are now generally acknowledged, as within a few years several mills have been constructed on this principle. The Bramah Press is

also used for extracting the oil from cocoa nuts with equal success, and a great many have been exported to Ceylon and other parts for the purpose. Machinery.

The cocoa nuts are first ground under runners or edge-stones into the state of pulp, which is put into hair bags, and submitted to pressure. The Presses are made to act vertically, and the bags are placed between horizontal plates so as to fill the space between the follower and the top of the frame. When the pressure is applied, the oil makes its escape through the bags and runs over the edges of the plate down to the follower, on the upper side of which channels are made to conduct the oil to an aperture connected with the copper pipe, which conveys it to the reservoir. The copper pipe, which of course ascends and descends with the piston, is made to slide in another large tube, so that the communication with the reservoir is perfect, whatever may be the elevation of the follower.

These Presses are constructed with two injection pumps, of one and two inches diameter, in order that a greater power may be applied at the completion of the action of the Press, when the resistance becomes greater. The levers which work the pumps are also made to shift, so that several degrees of power may be produced, as the state of the nut may require. In a Press which was constructed by Messrs. Bramah, under the direction of Thomas Hallyn, Esq., for the Island of Ceylon, the piston was eight inches diameter, and injection pumps one and two inches. The areas of the Press and two injection pumps are as the squares of their diameter in one case, viz. as 4:64, or as 1:16, and in the other, with the smaller injection pump, as 1:64: which constitutes the hydrostatic power of the Press. The mechanical power of the lever is as 1:10, when the pin or fulcrums are in the outer holes, and as 1:20 when in the others: so that by the multiplication of the ratios, the four hydro-mechanical powers will stand thus: $16 \times 10 = 160$ to $1:16 \times 20 = 320$ to $1:64 \times 10 = 640$ to $1:$ and $64 \times 20 = 1280$ to $1:$ which are in proportion to each other as 1.2.4.8. A man, whose weight is 150, will therefore be able to exert a force with this apparatus of 82 tons.

In using the Press, the action is commenced with the two-inch injection pump, the pin of its lever being in the outer hole, in order to save time. When the resistance has become greater than the power can overcome, the pin of the lever is fixed in the outer hole, and the action continued; when, however, this power is insufficient to overcome the resistance, recourse must be had to the one-inch injection pump with the pin of the lever in the outer hole, and finally the utmost power of the Press exerted, by shifting it to the inner hole.

The oil thus obtained from the cocoa nut, when it arrives in this Country, is in a white congealed state, at the usual temperature of the atmosphere. It is employed for various purposes where oil or fat is required, but more particularly as a substitute for oil in lamps, as it is considerably cheaper, and burns with a clear bright flame. In using it in lamps in the state in which it arrives in this Country, it is necessary to render it previously liquid, its own combustion will then generate a sufficient portion of heat to allow of the capillary attraction going on without any further trouble, if the lamp is constructed so that the reservoir of oil is sufficiently near the burner. This difficulty in its application as oil has been overcome by an improved process of refining it, for which a patent was taken out in 1831. It consists in separating by

Manufactures. extreme pressure the fluid part or oil from the solid part ; by this means not only the oil is so improved as to be fit to burn in any lamp, but the residue is sufficiently solid to make very good candles. It burns with as good a light as spermaceti, and is very much cheaper, so that its use is now becoming very general, as may be judged from the greater quantity imported in this Country in the year 1832 than in 1831, which is about the time the invention came into notice : the former amounting to 10,808, and the latter 4,328.

(513.) *An Account of the Quantities of Olive and Palm Oil imported into and exported from the United Kingdom, and cleared for Consumption, the Rates of Duty, and the Net Revenue thereon in each Year, commencing 5th January, from 1820 to 1831, both inclusive.*

Rolling and Hammer Mills.

Rolling and forge mills. (514.) The terms rolling and hammer mills have been given to the Machinery employed in the reduction and manufacture of iron and other metals, although the operation in which they are employed differs entirely from that to which the term mill was originally applied, and intended to signify. The rolling-mill consists of two cylindrical rollers of iron or steel, which are put in motion by a water-mill or steam engine, and are so moved that they cannot recede from each other ; so that when the iron is placed red-hot between them it is drawn in by the revolution of the Machinery, and reduced to a thickness equal to the space between the surface of the rollers.

Machinery. The hammer-mill consists simply of a large hammer, raised by the power of Machinery, by which a greater blow can be given than by manual labour.

The use of these mills in the manufacture of iron is very important : first, by depriving the iron of the carbon which is combined with it when in the shape of cast iron, to render it malleable ; and, secondly, by reducing it into bars of any figure that may be convenient for the purposes to which it is intended to be applied.

Fig. 1 and 2, pl. xli. is a front and side elevation of a rolling-mill for making flat bars. A A A A are strong cast iron frames, resting upon iron bars *a a*, in the masonry to which they are secured by strong bolts *b b*. The masonry B B rests upon the foundation of the mill, which is required to be very secure : where the ground is bad it is necessary that the brickwork should be carried down ten or twelve feet, and in some cases piles are driven. C C are two other frames, which give support to the pinions P P, by which the motion is conveyed from one roller to the other : they have a bearing on the iron plate *a a*, and are securely bolted to the masonry. R R R' R' are the rollers ; the lower one of which receives motion from the engine, and communicates it by the pinions P P to the upper one, which is thus turned in the opposite direction.

D D are couplings, which unite the pinion shaft to that of the rollers, in such a manner as to allow an elevation or depression of the upper roller, so that the rollers may be adjusted to the required dimensions of the bars without affecting the action of the Machinery. In iron Manufactures this adjustment is not generally required, as the bars are all made to given dimensions, which are not commonly deviated from. In this case the pinions do not require to be placed in another frame, but are situated on the roller shafts at the outside of the frames. When the adjustment required is very small it is commonly done with the pinions on the roller shafts, in which case the pinions are required to have large and long teeth, so that a slight alteration in the pitch line will not sensibly affect their action. This method is, however, attended with an extreme liability to break the teeth when in shallow gear, from the immense blows to which they are subject when the iron is first applied.

The cast iron frames A A are grooved inside, so as to admit of other frames being moved up and down in them. One of these is seen at E E, fig. 2. F F F are screws which work in the head of the cast iron frames, by means of which the sliding part E E can be lowered or raised, and at the same time the upper roller. Some means are required in large mills, to keep the rollers in the proper position after being adjusted, otherwise by their own weight they would remain resting upon the lower roller.

This is effected in the mill represented in the drawing, by weights W W, suspended to a lever, at the other end of which are attached vertical rods *r r*, which pass up through the framework of the Machine to the lower brass of the rollers : they are thus pressed with a force or weight greater than that of the rollers, and consequently, should the adjusting screws F F be elevated, the upper roller will follow, and the space between the rollers will indicate the dimensions of the bar to be rolled. Another very important reason for causing the rollers to follow the adjusting screws is, that if they remain resting on the lower one when the iron is introduced they are thrown up with such tremendous force against the upper bearing as to endanger the breaking of the

Manufac-
tures.

Machinery, and even of the rollers themselves, which is an accident that sometimes happens even with the greatest caution, in consequence of the enormous power which is required to put in motion this kind of Machinery.

Rollers are usually made of cast iron, and are very exactly turned on their surfaces, and also in their necks, that they may work perfectly true when put in their places. The most common way of turning them is, first to mount the roller in a strong turning lathe, by holes or centre-points made in the ends, and by that means to turn the two necks truly cylindrical; afterwards to put the roller in its proper place in the rolling frame, and placing brasses over the necks; they then are held down by blocks fitted under the pieces which retain the gudgeons of the upper roller, and in this situation the mill is put in motion, and a bar of iron being fixed up for a rest, the surface of the roller is turned true, in the same manner as if it were in a lathe, with this advantage, that it is certain to be exact, being formed from the same bearing on which it is afterwards intended to work.

Casting
rollers.

(515.) In casting a roller, the mould should always be placed at a considerable depth beneath the orifice where the metal is poured in, so that the pressure of a column of fluid metal may be obtained to consolidate the casting, and render it free from those air-holes or porous places which will sometimes occur in metal cast in the ordinary way. The long piece of metal which filled the aperture through which the metal ran, and which composed the column above alluded to, is left adhering to the roller, and is cut off afterwards. Casehardened rollers must be used when it is required to have a very fair surface, *viz.* for such purposes as rolling iron, to make thin plates for tinning: also the large rollers for gold and silver, such as are now used in the Royal Mint: rollers for making tinfoil, steel plate for saws, and for many other purposes. Cast iron rollers are not hardened by a subsequent process, as in casehardening wrought iron, but are cast in that state by employing iron moulds.

A cast iron cylinder of three inches thick, and its diameter equal to that of the roller, is bored out with great accuracy, and fitted with ends proper to form moulds for the necks required at each end of the roller. It is buried in the sand of the foundry, and when the metal is run into it, the rapid transmission of heat through the iron mould causes the metal in contact with it to cool sooner than the other parts of the mass, which has the effect of rendering the surface of the roller very hard. In turning a roller of this kind the centres must be chosen so that the circumference turns as true as it will admit of, and then a very small quantity being taken off will render it perfect. This care should be taken for two reasons: first, that less will require to be removed to make it true, which is important, from the difficulty of getting tools sufficiently hard to touch it; and, secondly, that if the metal be unequally reduced, or more on one side than the other, the hardest part will then be cut away, and the roller will have a hard and a soft side, and will in consequence soon wear out of the circular figure, and require a second turning. The less metal there is turned off a casehardened roller the better, because the hard part is only a case of little thickness, and most hard at the surface.

Operation
of rolling.

(516.) The operation of the rolling-mill is so simple as scarcely to require any description. The metal is heated in a reverberating furnace, when it is in large masses;

and for smaller pieces a kind of oven is used, in which the coke is laid on the bottom or floor of the oven, without any grate bars, and the draught of air being by this means less rapid, it gives a slight and very regular heat, and therefore does not waste the iron by burning it to scales, as a great heat and current of air will do. This oven is proper for heating plates, hoops, or small bars, to be rolled a second and third time; but for rolling large masses a stronger heat is required that the metal may be consolidated, and all flaws or cracks securely closed.

Machinery.

The iron being heated in the furnace to the proper degree for the purpose which is intended, it is presented to the rollers, which are previously adjusted to the thickness of the piece to be rolled. If this is not attended to, and the workmen attempt to reduce the iron too much at one time, there is danger of breaking some part of the Machinery, or stopping the mill whilst the iron is only half passed through, which is a very disagreeable accident, as it requires a considerable power applied to the screws to turn them back sufficiently to relieve the rollers.

When the iron is placed on the shelf S in front of the rollers, their motion will draw it through, and as they cannot recede from each other the metal is reduced to the exact thickness of the space between them, increasing in length, but not at all in breadth: the iron is caught by another workman behind the rollers, and returned over the top roller to the first man, who passes it through the next opening of the rollers; it is again returned to the first workman, and the operation is thus continued until it is reduced to the required shape and dimensions.

Fly wheels are more required in rolling-mills than in almost any other kind of Machinery, because the resistance to be overcome is so variable, being at one moment very great for a large piece of iron, then smaller whilst it is passing through a second time, because then it is to be less reduced; and in the interval of returning the iron there is no other resistance than that of the friction of the Machinery. Again, when the iron has been passed through several times, the resistance is greatest of all, because the metal has become harder, both by the compression it has undergone, and from being gradually cooled; also the metal being thinner will not yield so readily to the pressure as when in a larger mass.

In order to increase the momentum of the fly wheel it is usually put upon a distinct shaft to that of the lower roller, and receives motion from it by cog wheels, and is thus made to revolve with great rapidity.

(517.) *Rolling iron plates.*—Iron plates, when of considerable size, such as those used for steam engine boilers, tanks, or other large vessels of wrought iron, are rolled from blooms or half-blooms, made under the forge hammer. The blooms are nearly of the length of the intended plate, their breadth about one-half or one-third as much as their length, and of a thickness to contain as much metal as will make two, three, or four plates. These pieces, when heated to a white heat, are presented breadthwise to the rollers, and passed through several times at the same heat, until the breadth of the bloom being extended two or three times becomes equal to its length. The thick, square plate thus formed is now cut up by shears across into two or three pieces of about the same size as the first, but in a direction which will make what was the length of the first piece to be the breadth of the second. These pieces being heated and rolled again become extended to the size of the required plates:

Rolling iron
plates.

Manufac-
tures.

the reason of thus dividing the operation is, that the rolling only extends the metal in the direction in which the rollers move, and not at all in breadth: but by this means the particles of iron being drawn by the sides of one another, acquire in a degree a fibrous texture, which is desirable in bars, rods, hoops, &c., but not at all in plate, as this should be equally strong in either direction; therefore by rolling it first one way and then the other, the grain, as far as it is produced at all, is in both directions. There is no doubt that better plate would be made if the slabs or original pieces were cut to the proper proportion of length, breadth, and thickness to form only one piece: then rolling it alternately length and breadthwise every time it is passed between the rollers, and continuing thus until the plate is finished, a better grain or texture would be acquired, because by the former method it will be weaker one way, in consequence of the grain produced by the last rolling.

Plate
rollers.
Pl. xli.
Fig. 3, 4.

(518.) In fig. 3 and 4 is given a side and front elevation of a pair of plate rollers. R R R' R' are the rollers, which are made of cast iron, casehardened, and are turned perfectly true in their bearings. As the adjustment of plate rollers is not generally required to be of great extent, the pinions P P, which communicate motion from one to the other, are placed upon the roller shafts. The adjustment is effected by screws S S, to elevate or depress the frames F F, which carry the brasses of the upper roller. When the rollers are in use, a spanner is placed upon each of the nuts of the screws, and after the iron is passed once through the mill, the workman who stands in front to introduce the metal, turns the nut which is nearest to him on his left-hand side, whilst his mate, who receives it and hands it back again to him over the roller, turns the nut on the opposite corner of the same frame. The workman in again passing it through gives the nut another slight turn, and the operation is thus continued until the plate is reduced to the required thickness.

Iron plates which are employed for tinning require to be of the best English iron, and some of the thinnest are made from foreign iron. The original bars are drawn out by the forge hammer into bars five inches broad and half an inch thick, which are cut into lengths of eleven inches, by shears. These pieces are then heated in an oven, and passed breadthwise through casehardened rollers, which operation is repeated until they are extended to twice the length of the intended plates; the pieces are then folded, and set on their edge in the furnace till properly heated, when they are rolled double, the fold being put in first; they are thus extended to twice the length of the intended plates.

Two men with strong tongs now tear the two leaves asunder at the fold, and fold each again, separately putting one into the other, like two sheets of paper. In this state they are heated and rolled four thicknesses together, the next time eight, and so on, until the plate is reduced to the required thickness. In manufacturing the thinnest kind of plate, such as that used for tagging laces, sixteen leaves are rolled together. In folding the plates, care is taken every time to put a new surface of metal outside, otherwise those which are constantly reduced by the pressure of the adjacent leaves, would at length become grained on the surface; but by continually gaining new surfaces, which are smoothed by the immediate tact of the rollers, those which are laid against them are also rendered smooth. A small quantity of oil is sprinkled between the leaves when they are first put in,

which instantly spreads over the whole surface and prevents any adhesion; the plates are squared by the shears every time before they are folded, to remove those parts which, by projecting over the edges of the other leaves, are not so much reduced.

After being finished, dressed square, and the surface scoured, the plates are rolled singly, between a pair of casehardened rollers without being heated; they are by this operation extended but little in size, although rendered much harder and less flexible.

(519.) Mr. William Daniell of Abercarne, Monmouthshire, took out a patent in the year 1822, for an improvement in rolling iron plates for tinning, which consisted in rolling the iron perpendicularly between rollers with grooves of different gradations. The iron is cut by a pair of shears into pieces of four inches and a half square, and passed singly through the first groove of the rollers, it is then passed through the second, and so on successively until it is reduced to a proper thickness for the manufacture of the plate. By means of rolling the iron perpendicularly, the inventor states that the inside of the piece of iron is brought to the surface, and any imperfection which it contains, instead of being dispersed and intermixed throughout, is forced to the edge and ends. The quality of the iron for tin plates, he states to be thus much improved, and the number of tin plate wasters thereby reduced.

Machinery

Daniell's
patent
rollers.

(520.) In rolling and slitting iron for nail rods or small hoops, the iron is brought from the forge hammer in bars of a size proportionate to the nail rod intended to be made; these are cut into length by shears, heated in a furnace, and repeatedly passed through rollers until they become the thickness of the square of the intended rod. In this state it is presented to the slitters, which are rollers resembling in shape the right-hand part of the rollers in fig. 1; each of the openings is of a width equal to the thickness of the rod, and the corresponding ring of the other roller projects some distance within the opening, as seen in the figure; by this means when one of the bars above mentioned is introduced between the guide bars of the slitters, the ring of one roller presses a corresponding breadth of hot metal into the space between the rings of the other; this being performed in the same manner by both, completely divides the bar into several rods of the same breadth with the rings of the rollers. A small leaden pipe is fixed over the cutters, which, being perforated with holes, constantly lets fall a supply of cold water upon the rollers to prevent them from becoming hot, and thus losing their hardness, which alone preserves their figures under the intense pressure they have to sustain in dividing the iron. This apparatus for cooling the rollers is common in most rolling mills, to prevent the ill effect which would result from their getting hot; and guide bars also are placed near the rollers to force the rods when cut out of the grooves between the rings of the collar, which they would not otherwise quit after being so forcibly pressed into them by the rings of the opposite roller. In making small hoops, the rods, as soon as they are formed, are put through the plane rolls again and flattened into a hoop.

Rolling iron
for nails,
hoops, &c.

In the country, iron hoops are made from bars reduced in rollers which are cut into lengths, heated and passed through slitters which divide them into three or four rods; they are then immediately presented to the casehardened rollers and flattened into hoop iron. In London, where a vast quantity of old hoops can be procured, they are remanufactured, and make the best

Manufac-
tures.

description of hoops. The Victualling Board alone consumes many hundred tons annually for the service of the navy. The old hoops are made up into faggots, and shingled or welded into a bloom at one heat by a forge hammer. The blooms being again heated, are rolled out into bars and cut into two or three lengths, according to the sizes of the intended hoops; these pieces are heated a third time, slit into rods as above described, and then formed into hoops by casehardened rollers. By successive improvements, it has been found that two heats are sufficient, the first for shingling and forming the bars, and the second for slitting and flattening the hoops. Vat hoops or others about two inches in width do not require to be slit, but are at once carried from the bar rollers to the plain rollers which finish them. The piles for shingling must not be made too large or the hoops will not retain sufficient heat to be sound; about forty-two pounds is a proper quantity. The mill for this manufacture must of course have great power, and the rollers should move with sufficient velocity to enable the iron to be got through while sufficiently hot.

In rolling iron for nails, one of the rollers is made with teeth on its surface resembling a ratchet wheel, which divides the rod into pieces of the length and shape of the intended nail, the size and shape of the latter depending on the description of teeth upon the surface of the roller.

Rolling
brass, cop-
per, &c.

(521.) The rolling-mill is not confined to the laminating of iron, but is likewise employed very extensively for reducing brass, copper, tin, lead, as well as gold and silver. The latter metals are scarcely reduced by any other means than rolling, as this method makes no waste, is more expeditious, and produces better work than hammering or any other method, particularly when an equality of thickness and even surface is required, as in the case of gold and silver. In this description of work the rollers are made of steel hardened and polished on the surface with the greatest nicety, that they may produce a perfect surface on the metals which have to be passed through them.

Hammer-
mills.

(522.) *Hammer-mills* are commonly used in the conversion of cast iron into malleable iron. The cast iron after being decarbonized in a reverberating furnace, becomes a mass of grains of about the size of a mustard seed, which have very little adhesion for each other, and is full of interstices. The use of the hammer-mill is to beat these grains into one mass, which is done at a welding heat. Hammer-mills are also employed in forging the heavier description of iron work, such as anchors. They are of two kinds, termed the lift hammer, and the tilt hammer; the former of which is supported at the extremity and raised by a wheel underneath, and the latter is supported at about one-third of its length, and is elevated by a wheel above, which acts upon the part of the shank extending beyond the point of support.

Fig. 5, 6.

In fig. 5, 6 of the plate are given elevations of a lift and tilt hammer. A A A, fig. 6, is one cheek of a framework which is strongly secured to the masonry of the foundations, and to a similar cheek on the opposite side of the hammer by bolts, *a a a*, &c, and thus forms a firm bed for the plumber blocks B, C. S S is the shaft of the hammer which is made of timber secured by wrought iron rings *b b b*; this is fitted into a cast iron socket D, with trunnions or axles cast upon it, which turn in brasses in the plumber blocks C. E is the wheel by which the hammer is elevated; it is cast with ears or tappets *c c c* upon it, which during the re-

volution of the wheel engage the end of the shaft, and continue to depress it until, by the continuation of the motion, it is disengaged, and the hammer head falls with considerable force upon the anvil. By this means a repetition of blows is kept up, which are of course much more effective than can be accomplished by manual labour.

When a very heavy blow is required, the most convenient construction is the lift hammer, shown in fig. 5. Here, A B is the hammer, which is composed of a solid mass of cast iron, weighing from three to four or five tons. At the extremity, A, are two pieces cast, running at right angles to the shaft of the hammer, which cause it to resemble, when viewed from above, the shape of a T; the end of one of these pieces is seen at C in the figure; it has, at the lower part, a circular projection, which rests, in a corresponding indentation in the framework D D, and serves for the support on which the hammer turns. In consequence of a liability of the end of the hammer to spring up after a blow is struck, a wrought iron band or strap is passed over a projecting part on the end of the hammer and over a similar one on the framework, which prevents any such effect taking place. The elevation of the hammer is effected by the wheel W, by the shape of which it will be seen that the hammer will be raised three times during one revolution of the shaft. The part *c c* which engages the wheel is not cast upon the hammer, for being liable to wear from the constant friction of the wheel, it is made in a separate piece, which is attached to the hammer by bolts and nuts, and can thus be readily shifted and replaced when required. The surface of the wheel which comes in contact with this piece, is composed of steel, let in and secured to it by wedges and keys.

In hammer-mills, as well as rolling-mills, the use of the fly wheel is much required in consequence of the variability of the power which is exerted upon them. It is very common with tilt hammers, in consequence of the suddenness with which they come into action, to connect the parts of the fly wheel shaft by a wooden spring coupling, which takes off the shocks that would otherwise be brought upon the engine.

Foundations for hammer-mills require great attention, otherwise the repeated blows of the hammers would cause the anvils to settle. To remedy this, the foundation of the frame is carried down ten or twelve feet into the ground, so as to form a heavy mass of masonry, and the anvil rests upon a large wooden pillar, strongly secured by wrought iron rings; this is supported and forms part of the masonry above alluded to, so that no settling can take place without the whole mass being moved together.

Within a few years it has been discovered that the process in which the hammer-mill is employed, *viz.* that of uniting the particles when separated in the puddling process, can be performed efficiently by rollers, and the hammer-mill has in consequence been done away with in some very extensive iron manufactories. This fact was first discovered by the late Mr. Wilkinson, who employed in his extensive works at Brosely, in Shropshire, a pair of enormous rollers, to which a reciprocating motion was given by a steam engine; they were five feet in diameter, nearly ten feet long, and weighed nearly five tons, although cast hollow like garden rollers; sectors were fixed on the ends of the gudgeons, by which one roller turned the other about one-third of a revolution, and then moved back again. The circumference of the

Machinery

Manufac-
tures.

rollers were cast with grooves gradually diminishing from one end to the other. The mass of iron to be rolled was collected into a ball in the furnace, which was taken out and passed through the greatest of the grooves. When it came through, a workman at the opposite side removed the ball to the next smallest groove, which by the returning motion was carried back to the front; the front workman then returned it in another groove, and so on, passing it successively through the different grooves, until by gradual consolidation it was reduced to an imperfect bar of malleable iron. A number of these being cut into lengths, were made up into faggots or piles, and by a pair of rotating rollers were finished into bars. Mr. Wilkinson had a patent for this Machine, but it was afterwards found that common rollers would effect the object better. The rollers now used for the purpose do not differ much from those shown in fig. 2 in the plate, except that the number of grooves is much greater, and that the larger ones, where the metal is first put in, are made of a circular figure, with teeth at several places on the circumference by which the metal is more readily drawn in. The use of these rollers is very similar to those we have described above, the ball of metal is taken from the furnace and passed through them ten or twelve times, being passed through a smaller groove each time, so as to compress it in a greater degree every time till it is at last reduced to a square bar. The last groove has also teeth in different parts of the circumference, and at such dimensions and distances from each other, that they will indent so deeply upon the angles of the bars at every eight or ten inches of their length, as to render it easy to break them into short pieces when they come through. The pieces thus formed are piled four or more together and put into a balling furnace, and when heated are rolled into thin parallel bars, in which state they are usually sent to market.

The rollers are said to enclose the impurities of the iron rather than to expel them; but as rollers require much less power to give them motion than the hammer, it becomes worth the consideration of manufacturers to improve their construction and render them equal in effect to the hammer.

Saw-mills.

Saw-mills.

(523.) Saw-mills are of recent introduction in this Country, although they have been employed many years on the Continent. Their history, with that of the invention of the saw, is given at considerable length by Beckmann, in his *History of Inventions*, from which we quote those parts that appear most interesting.

In early periods of Society, the trunks of trees were split with wedges into as many and as thin pieces as possible; and if it was necessary to have them still thinner, they were hewn by some sharp instrument on both sides to the proper size. This simple but wasteful manner of making boards, has still been continued in some places to the present time. Peter the Great of Russia endeavoured to put a stop to it by forbidding hewn deals to be transported to the river Neva. The wood splitters perform their work more expeditiously than sawyers, and split timber is certainly much stronger than that which has been sawn; because the fissure follows the grain of the wood, and leaves it whole; whereas the saw, which proceeds in the line chalked out for it, divides the fibres, and by that means lessens its cohesion and

VOL. VII.

strength. Split timber, indeed, turns out often crooked and warped; but in many cases to which it is applied, this is by no means prejudicial, and the fault may sometimes be amended.

(524.) The inventor of the common saw has, by the Greeks, been inserted in their Mythology, and placed among those whom they have honoured as the greatest benefactors of the earliest Ages. By some he is called Talus, and by others Perdix: Pliny ascribes the invention to Dædalus; but Hardouin, commenting on the passage in which it is mentioned, considers Talus rather than Dædalus as the inventor. Diodorus Siculus, Apollodorus, and others, name the inventor Talus. He was son of a sister of Dædalus, and was placed by his mother under the tuition of her brother to be instructed in his Art. Having, it is said, once found the jawbone of a snake, he employed it to cut through a small piece of wood, and by this means was induced to form a like instrument of iron, viz. a saw: this invention, which greatly facilitates labour, excited the envy of his master, and instigated him to put Talus to death privately. We are told, that being asked, when he was burying the body, what he was depositing in the earth, he replied, "a serpent." This suspicious answer discovered the murder; and thus, adds the Historian, a snake was the cause of the invention, of the murder, and of its discovery.

The saws of the Grecian carpenters had the same form, and were made in the same manner as ours are at present. This is fully shown by a Painting which is still preserved among the antiquities of Herculaneum. Two Genii are represented at the end of a bench, which consists of a long table resting upon two four-footed stools. The piece of wood which is to be sawn through is secured by cramps. The saw with which the Genii are at work has a perfect resemblance to our frame saw; it consists of a square frame, having in the middle a blade, the teeth of which stand perpendicularly to the plane of the frame. The piece of wood to be sawn extends beyond the end of the bench, and one of the workmen appears standing and the other sitting upon the ground. The arms in which the blade is fastened have the same form given to them as at present. In the bench are seen holes, in which the cramps that hold the timber are placed; they are shaped like the figure 7, and the ends of them reach below the boards that form the top of the bench.

(525.) The first introduction of saw-mills seems to have been on the Roer, a river in Germany, in the IVth Century; for although Ausonius speaks of water-mills for cutting stone, and not timber, it cannot be doubted that these were invented later than mills for cutting out deals, or that both kinds were erected at the same time. Pliny conjectures that the mill for cutting stone was invented in Caria, at least he knew no building incrustated with marble of greater antiquity than the Palace of King Mausolus at Halicarnassus. This edifice is celebrated by Vitruvius for the beauty of its marble; and Pliny gives an account of the different kinds of sand used in cutting it: "for it is the sand," he says, "and not the saw which produces the effect." The latter presses down the former, and rubs it against the marble, and the coarser the sand is the longer will be the time required to polish the marble which has been cut by it. Notwithstanding these facts, there is no account in any of the Greek or Roman writers of any mill for sawing wood, and as the writers of more modern times speak of saw-mills as new and uncommon, it seems

Machinery.

Invention
of the saw.

First inven-
tion of saw-
mills.

Manufac-
tures.

either that the oldest construction of them has been lost, or that some important improvement has made them appear entirely new.

Saw-mills, although employed in many parts of the Continent as early as the XVth and XVIth Centuries, were violently opposed in England, under an idea that the sawyers would by the use of them be deprived of the means of subsistence. For this reason it was found necessary to abandon a saw-mill erected by a Dutchman near London in 1663; and in the year 1700, when a person of the name of Houghton laid before the nation the advantage of such a mill, he expressed his apprehension that it might excite the rage of the populace. What he dreaded was actually the case; for in 1767 or 1768 an opulent timber merchant, by the desire and approbation of the Society of Arts, having caused a saw-mill driven by wind to be erected at Limehouse, under the direction of James Hansfield, who had learned in Holland and Norway the art of constructing and managing Machines of that kind, a mob assembled, and pulled the mill to pieces; the damage, however, was made good by the County, and some of the rioters were punished. A new mill was afterwards erected, which was suffered to work without any molestation, and which led to the erection of others. It appears, however, that this was not the only mill of the kind then in Britain; for one driven by wind had been built at Leith in Scotland some years before. From this period, particularly since the improvements in the steam engine, the number of saw-mills has increased very rapidly, and they are now to be met with in almost every large timber merchant's yard.

Construc-
tion of
saws

(526.) *Construction of saws.*—Saws are constructed either of iron simply hammered and hardened, or of tempered steel ground bright and smooth. They are known to be well hammered by the stiff bending of the blade, and to be well and evenly ground by their bending equally in a bow. The edge in which the teeth are made is always thicker than the back, because the back has to follow the edge. The teeth are cut and sharpened with a triangular file, the blade of the saw being fixed in a whetting block, and after the teeth are filed, they are turned out of the right line, that they may make the kerf or fissure the wider, to enable the back of the saw to follow more readily. This is termed setting the teeth.

In sawing valuable timber the teeth are not turned out so much (or as the workmen term it, set so rank) as for coarse cheap stuff; because the ranker the teeth the more stuff is lost in the kerf. The saws used in cutting stone have no teeth; these are generally very large, and are stretched out and held evenly in a frame.

Pit saws.

Before saw-mills came into use the work was performed by two men with a saw, termed the pit saw, which is the one chiefly used in the employment denominated sawing. To perform the work, the timber is laid on two rollers over a rectangular pit, denominated the saw-pit; and the saw, which is of considerable length, with a cross handle at each end, is worked by the two men, one of whom stands on the timber to be cut, and the other in the pit. As they proceed with the work wedges are driven at proper distances from the saw to keep the fissure open, which gives more freedom to the motion of the saw. When they have advanced as far as the end of the pit the timber is moved forward on the rollers, which operation is repeated until the saw has arrived at the end of the timber.

Saw-mill.

(527.) *Saw-mill.*—The common saw-mill which is

generally employed in cutting timbers into planks, consists of a square wooden frame, in which a number of saws are stretched; this frame rises and falls in another wooden frame, secured to the foundation of the mill, in the same manner as a window-sash rises and falls, motion being given to it by a crank. The timber to be cut is placed upon a horizontal bed or carriage, sliding upon the floor of the mill, which being sufficiently narrow to pass through the inside of the vertical or moving saw frame, will carry the tree through and subject it to the action of the saw; the carriage is provided with a rack, which is engaged by the teeth of a pinion, and thus gives the means of advancing the carriage. The pinion is turned by means of a large ratchet wheel, with a click moved by levers connected with the saw frame; when the saw frame rises the click slips over a certain number of teeth of the ratchet wheel, and when it descends to make the cut, the click turns the ratchet wheel round, and advances the wood forward just as much as the saw cuts during its descent. The trees are generally dragged up an inclined plane, through a door at one end of the mill, and being placed upon the carriage, they pass through and are divided by the saw into two or more pieces, which are carried forward and passed out at a door on the opposite side of the mill.

Fig. 1 and 2, plate xlii. is an elevation of a saw-mill, constructed by Mr. Hague of Ratcliff for the Dutch Government, for the purpose of cutting planks, which is very ingenious and simple in its construction. A A A are timbers built securely in the foundation of the mill, to which the cast iron framework B B B is bolted by strong bolts and nuts at a a a a. This cast iron framework is a great improvement upon the wood framework hitherto employed, from its superior stiffness; and as the guides for the saw frames and other parts have to be attached to it, which are of iron, the liability of loosening, which always occurs when iron and timber are united, from the shrinking of the latter, is avoided. Motion is communicated to each Machine by leathern belts, very judiciously employed instead of cog wheels, because they will stop and yield if any thing should get foul in the movements, while toothed wheels would in a similar case break every thing to pieces. In fact, all Machinery, where the quantity of work is not constant, should be driven by belts in preference to cog wheels, for the reasons above stated. C C is a horizontal shaft, which has a bearing at each end in the sides of the framework. It has attached to it the fast and loose pulley D D, E E, which receives the motion from the steam engine when required, and a fly wheel F F F, of which one is necessary to every saw frame, independently of that employed at the engine. G G G G is the frame in which the saws are fixed; it is guided in its vertical motion by moving on square bars b b, attached to a projected part of the cast iron uprights or framing. This is a very excellent and simple method of guiding the motion of the saw frame, as it is attended with little friction, and any looseness that may take place from wear is immediately corrected by screwing up the nuts c c c c.

In some saw-mills friction rollers are employed for diminishing the friction between the saw frame and the channel it moves in, which are so placed that the frame is completely guided by them without rubbing against any thing else. They generally consist of four pair of rollers placed horizontally, all of equal diameter; each pair being connected by a common spindle, the length of which is determined by the breadth of the saw frame. The centres or bearings are fixed in such a

Machinery.

Pl. xlii.
Fig. 1, 2.
Saw-mill by
Hague.

Manufac-
tures.

manner as to admit of adjustment, in order to confine the saw frame to its true position, and give a steady motion. Similar rollers, to be applied at the sides of the frame, have also been proposed, but they appear to be attended with a liability to get out of order by wear, which gives an unsteady motion to the saw.

The saws are fixed and stretched in the frames by wedges, which are driven above through mortises in the upper part or bar of the saw. In this way any number of saws may be fixed on the frame, and at any distance from each other. It is, however, generally necessary, in consequence of a tendency which is given to twist the saw in the plane of its direction by tightening the wedges, to have pieces of wood of the exact thickness of the planking required placed between them, with similar pieces outside, which are all screwed firmly together by screws in the sides of the saw frame.

Mr. Brunel's method of fixing and tightening saws.

(528.) A very ingenious method of fixing and tightening the saws is employed in the saw-mills in the Royal Arsenal, Woolwich, invented by Mr. Brunel, who has devoted much time to the subject of saw-mills, and to whom we are indebted for many important improvements. By his method a number of saws can be very speedily removed, and a new set of sharpened ones put in. Each saw has pieces of metal rivetted to it at each end, which are formed like hooks. The hook at the lower end of the saw falls into a proper recess made in the lower cross bar of the frame, and the upper hook is engaged with the hook of a shackle or link, which hangs upon the upper cross bar, and has wedges through it, by means of which it can be drawn tight to strain the saw. As the tension of the different saws is in some measure uncertain, when merely depending upon driving the wedges of the shackles by a hammer, Mr. Brunel has employed a very ingenious steelyard, which not only shortens the time required for wedging them up, but exhibits the degree of tension which is given to the saw. It consists of the following parts. A strong axle is extended across the fixed frame, in which the saw frame slides, and above the top of this frame, from one side of this axle, a lever proceeds, which has a weight fixed at the end, and from the opposite side of the axle proceeds two short levers, which are connected by links with a strong cross bar, situated just over the upper cross bar of the saw frame, when it is at its greatest point of elevation. This cross bar of the steelyard has a link or shackle upon it, which can be united by a key with any of the shackles upon the upper cross bar of the saw frame, which shackles are as before mentioned united by the hooks with the upper end of their respective saws; and by this means the lever with its weight becomes a steelyard to draw up any one of the saws with a determinate force. In using this apparatus the band or strap of the crank shaft is cast off to stop the motion of the saw frame, the crank is turned round to elevate the frame to the highest point; two wedges are then put in between the saw frame and a fixed part of the stationary frame, and this holds the saw frame fast while the steelyard is applied, otherwise it would tend to strain the crank and crank rod. The sharp saws are now put into the saw frame, by hooking them upon the lower cross bar, and uniting the hooks to the shackles on the upper cross bar, and pieces of wood are put between the saws according to the gauge of the wood which is intended to be sawn, and bound fast by screws, as has been described in the mill shown in the drawing. The loaded end of the steelyard is now lifted up by a rope passing over a pulley,

and the link upon the cross bar of the steelyard is united with the shackle of one of the saws; then by allowing the steelyard to descend, it stretches the saw, and the wedge being thrust in by the hand, as far as it will go, thus retains the saw at the tension to which the steelyard had stretched it. The shackle of the steelyard is then disengaged from the saw, and removed to the next, and thus in turn all the saws are strained more equally than can be effected by simple wedges.

Machinery.

Referring again to fig. 1 and 2. H H H is the section of the timbers composing the floor of the mill; I I I are cast uprights, which are bolted down firmly to the floor, and carry at their upper part horizontal rollers, upon which the timber is moved while passing through the mill. The timber is fastened at one end to a carriage attached to the rack seen at L, and at the other to a carriage which can be adjusted according to the length of the timber to be cut. M M is a rack by which the timber is moved on during the action of the saw, in the following manner. N N is a horizontal lever, which turns upon the point N, and receives a slight reciprocating motion from an eccentric *g* upon the crank shaft during the stroke of the saw, but in a reverse direction, so that while the saw descends, the end of the lever rises; *h* is a small arm attached to the lever in such a manner as to engage the teeth of a large ratchet wheel O O, while the motion is upwards, but in its descent simply passes over them without giving motion to the wheel. It has a small counterweight *n*, which causes the end of the arm to press gently against the teeth of the ratchet wheel *m*, in order that in its return it may not fail to engage them. It will then be readily seen, that during the descent of the saw, which is the time its action takes place, the lever N, by means of the eccentric, is moving the ratchet wheel round, from which, by a small pinion *p* upon its axle, which engages the teeth of the rack M M, the carriage and timber is moved gently forward towards the saw. The turning point of the lever N N can be adjusted to any part of it within the point *i*, where the eccentric rod is fastened, so that any degree of motion can be given to the timber according to the nature of the wood to be cut.

The part marked P P in the drawing is a guide for the timber while passing the saw frame, which causes the former to keep a direction parallel to the motion of the saw. The timber is pressed against the guide by means of a lever, (not shown in the drawing to prevent confusion,) one end of which is connected with a weight over a pulley, and the other to a roller, which is pressed by means of the weight against the timber, and keeps it in its proper position with respect to the saw.

When the timber has passed the saw, the carriage is returned by means of a handle *m* upon the spindle of the ratchet wheel and pinion, which is worked by a man; the click being of course thrown up clear of the teeth to allow of its motion in a reverse direction. In some mills this is effected by the engine; it, however, involves more Machinery than the necessity of the case requires, as a man can run it back in less than a minute.

(529.) *Circular saw-mills.*—The above is the description of mills generally employed for cutting timber longitudinally. Circular saw-mills are, however, sometimes used, and with considerable success, in cutting veneers. Mr. Brunel took out a patent in 1805 for improvements in the Machinery for sawing timber, in which he employed a large circular saw, composed of several pieces fitted together, by screwing them to a large flanch turned per-

Circular
saw-mills.

Manufac-
tures.

fectly true, which formed part of the axle of the saw; the holes through which the screws passed were cut in an oblong form, to admit of adjustment. When the plates have been thus fastened to the flanch, another detached flanch is laid upon the plates; and in order to make it fit and bear with equal force on each plate, several thicknesses of paper or leather of the size of the flanch are placed between it and the plates, and every thing screwed up tight by bolts and nuts.

The saw or saws, thus prepared, are placed in a frame at such an elevation that the bottom of their revolution is a little below the lower edge of the timber. The timber is placed in a carriage and moved towards the saw by a rack, in a similar manner to the common saw-mill.

Machine
for cutting
veneers
used in
Russia.

(530.) Circular saws of large dimensions are not commonly used in this Country, except for cutting veneers, which process is said to be performed in a much superior manner in Russia by a planing Machine. The construction of it is simple, combining the advantage of cutting the most valuable woods without waste, and very rapidly, to an extraordinary extent, and so thin that they have been employed for the covering of books, and for lithographic and other engraving. One hundred feet in length of veneering may be cut by this Machine in the space of three minutes.

The operation is begun by placing the timber from which the leaf is to be cut upon a square axle, when it is revolved and made circular by a turner's gouge. The blade of a plane of highly tempered steel, and rather longer than the cylinder, is fixed at the extremity of a frame of six or seven feet in length, in such a manner as to exert a constant pressure upon the cylinder, and pare off a sheet of an equal thickness, which folds upon another cylinder like a roll of linen. The frame to which the blade is attached is movable at its lower extremity, and as it is charged, it depresses in proportion as the mass diminishes in substance. That this depression may be progressive and perfectly regular, the inventor has appended a regulator to the Machine, consisting of a flat brass plate, preserved in an inclined direction, upon which the frame descends as the regulator itself is advanced. The motion is communicated to the cylinder by several cog wheels, which are turned by a crank.

Benchsaws.

(531.) *Bench saws.*—Although, as above mentioned, the circular saws of large dimensions are not commonly employed, the small circular bench saw is a most valuable instrument in large establishments, as in Government works. The saw is fixed upon an axle, and made to revolve by straps or bands with great rapidity. The wood being presented to it is cut by a continuous motion; and as this admits of far greater velocity than can be given to any reciprocating Machine, the circular saw cuts a surprising quantity of wood, not less from this circumstance than because it is always in action, whereas the reciprocating saw only cuts in one direction, and all the time occupied in the return is lost. These advantages, arising from the circular figure of the saw, are equally true whatever may be the diameter; but when the dimensions are large, several practical difficulties present themselves; such as the inconvenience of replacing a blunted or worn saw by a sharp saw, which of course must be more frequently repeated than in the reciprocating saw-mill, and other similar disadvantages, which greatly reduce their value.

The common bench circular saw is usually fixed in a horizontal table or bench, which has a cleft through which the saw comes up; the spindle being situated

under the bench, and across the direction of its length. Machinery
A segment or portion of the saw is left projecting above the bench, and the piece of wood being laid flat upon it is advanced forward to the saw, and cut with great facility, at the same time it is certain to be perfectly square; but if the sections are required to be at any other angle or bevel, the bench is inclined to suit it. A long parallel ruler is fixed down upon the bench, capable of being brought nearer to or further from the saw, and thus forms a guide against which the piece of wood is held; by this means the saw cuts always to the same width, but the width can be varied at pleasure.

The time of the introduction of this valuable Machine is not well ascertained. Circular saws for cutting the teeth of watch and clock wheels have been in use since the time of Dr. Hooke; but we do not know positively who first applied them to the sawing of wood: it is said to have been General Bentham who first introduced them into this Country. Mr. Taylor, of Southampton, used them in his manufactory many years ago; but it appears that Mr. George Smart, who has a manufactory on the Surrey side of Westminster bridge, was the first who employed them to any extent, since which time they have become very general for all kinds of purposes.

A great improvement in the method of mounting them was invented by the late Mr. Maudslay. The first saws were made with sharp conical points at each end of the spindle, which were received into conical holes in the ends of two screws fitted in the solid framework of the Machine; or the reverse, *viz.* the points were made upon the ends of the fixed screws, and the holes in the ends of the spindle; in either case both parts were made of hardened steel. But if this method is used on a large scale with a great velocity, the oil cannot be kept in the sockets, and the friction will then cause the points of contact to heat; by heating they expand, and thus increase the friction and the pressure, so that when once the effect of heating takes place it rapidly increases, until the metal becomes soft and will twist off the points. The conical form of the end of the spindle gives the oil a tendency to run up it, and thus escape from the point where it is chiefly wanted. This evil is avoided in the spindles proposed by Mr. Maudslay, which have double conical sockets: the oil is introduced by a small hole into the smallest part of the double cone where they join; by this means the centrifugal force draws the oil into the fitting, instead of throwing it out as in the common spindle.

(532.) *Sawing Machinery at Portsmouth.*—The most complete sawing Machinery in this Country is considered to be that used in the block Machinery at Portsmouth, also invented by Mr. Brunel, by which the timber is reduced from the tree to the proper sizes ready to be formed into blocks. The elm trees, of which the block is formed, is cut into proper lengths to form such blocks as the tree seems best adapted for, by two cross-cutting saws, one of which is a reciprocating and the other a circular saw.

The tree subjected to the action of the cross-cutting reciprocating saw is placed on a long frame or bench raised a little above the floor, on the end of which is erected a frame composed of vertical posts and a cross timber; through this frame the end of the tree is drawn by a capstan working in the middle of the room upon a vertical shaft turned by the steam engine. The end of the timber projects as much beyond the front of the frame as the part intended to be cut off, and is fastened from rolling sideways by a lever, which presses upon it and holds it down.

Manufactures.

Reciprocating cross-cutting saw.

The saw is a straight blade fixed into a wooden handle at each end to lengthen it; one of these handles is connected by a joint to the upper end of a lever, bent at right angles and having its centre beneath the floor; the horizontal arm of the lever is connected by a spear rod with the crank on the end of a spindle near the ceiling of the room, the motion of which is regulated by a fly wheel. By this means the saw has a reciprocating motion from right to left nearly in a horizontal position, and exactly across the log that is to be cut, resembling in its action the carpenter's handsaw. The teeth of the saw are of course on the lower side of the blade, and it acts entirely by its own weight. The Machine being at rest is prepared for work by fixing the log in the frame by the lever, so that the surface of the frame intersects the log at the place it is intended to be cross cut. The saw which was before lifted up by its handle to be clear of the log is now suffered to rest upon it in the place where the cut is to be made, and to guide it in first setting in, the back of the saw is received in a saw kerf made in the end of a piece of board, which is attached to the frame over the saw, but slides up and down to reach it at any height according to the thickness of the log. The Machinery is then put in gear, which causes the saw to reciprocate horizontally across the tree, and thus by its own weight cuts it through. As the saw gets into the tree it quits the guide above mentioned, which becomes less necessary as the saw goes deeper; a saw having no tendency to alter its course when cutting across the grain.

Circular cross-cutting saw.

(533.) The circular cross-cutting saw which is employed for the same purpose is more novel in its construction. The spindle is so mounted as to move in any direction parallel to itself, the saw continuing in the same plane; by this means it can be applied to any part, so that it will divide trees much larger than could otherwise be done by it. It is more expeditious and accurate in its performance than the one above described, for which reason the preference is always given to it in all cases where the size of the tree is not too great for its application.

Pl. xlii.
Fig. 3, 4.

Fig. 3 and 4. pl. xlii. is a plan and elevation of this Machine. A A is the tree intended to be sawn across; it lies upon a framing of timber B which supports it. Across the head of this frame a strong timber or ground sill C is framed, in which two uprights R S are erected; these with a cross beam at top form the frame which gives the means of confining the tree upon the bench while it is cut. The fixing of the tree is effected by means of a lever D, one end of which engages a bolt put in a hole in the post S of the frame to serve as a fulcrum, and the other end passes between the face of the post R, and a piece of wood *a*, which is bolted to it, and the lever being forced down upon the tree is kept down by a bolt put through a hole in the piece *a*, and also into the post. The other end of the lever is retained by a piece of wood similar to *a*, fixed to the post S; and by this means the tree is held steady while it is being sawn.

The roller, or capstan, T serves to advance the tree forward on the bench; it is turned by means of the handspike E, which has a small click engaging the teeth of a ratchet wheel *b*, fixed fast upon the axle or centre pin. The handspike being worked in the manner of a pump turns the roller about a few teeth of the wheel at every stroke, and by a rope wound on the

roller draws up the tree; it has a click *d*, which detains the teeth of the ratchet wheel, and prevents the roller running back after being moved by the handspike. The framing of wood, or bench, B is continued for some distance in front of the part S in order to form a support for the piece of timber which is cut off. It has a cross piece *f* bolted down to it which acts as a stop to the end of the tree; this piece is adjustable and serves to measure the quantity to be cut off; a space is left between the projected part F and the bench B, for the saw to descend into when it has divided the timber.

The saw, which is shown at G, is fixed on the end of a spindle *g* mounted in a frame consisting of two side beams H H, connected by cross pieces I I K L, and strengthened by diagonal bolts or ties *ee*; the upper cross piece is formed of iron, and its ends are jointed to the end of a frame M M, poised in the manner of a balance beam of a drawbridge, on a fulcrum supported by the fixed framing of the Machine, which consists of two posts N N, extending from the floor to the ceiling, and connected by a cross beam O O. By this means the saw can be moved in any direction at pleasure, but always preserves its parallelism. The saw receives its motion from the mill by the strap *h*, which passes over a pulley *i*, seen in fig. 3, contained in an opening in the iron top L of the frame H. It is fastened on a short spindle, which is exactly in a line with the joints connecting the two frames M M and H. Upon the same spindle is another pulley *k*, which gives motion by a strap to one on the spindle of the saw. Two small wheels *m m* are attached to the frame H to guide the strap, which can be adjusted, if necessary, in order to tighten it. *n n* are two pulleys which guide the main strap *h h*, which are placed near the centre of motion of the frame M M, in order that the tightness of the strap may not be materially affected by the alteration of the position of the saw. The workman governs the Machine by two winch handles V and W; the latter of these is on the end of an axle *w*, having two pinions upon it which engage racks on the end of two wooden rods Q Q. These rods are connected with the end of the great frame M M by the joint which connects the two frames together; so that by turning the winch W in one direction it elevates the saw, and in the other depresses it. In a similar manner, the winch V gives motion by a spindle *v*, upon which a pinion is attached which engages racks on the ends of two rods X X, jointed to the suspended frame H. Thus the position of the saw may be changed horizontally, or vertically, with respect to the timber. The two frames H and M are greatly strengthened by the rods Q Q and X X; for as these two pinions act equally upon the rods and thus move both sides of the frame alike, they preserve them from twisting, which would otherwise cause the saw to deviate from the parallelism. To produce this effect perfectly, it is, however, necessary that the pinions should fit the rack very accurately. Two rollers *y y* are fixed in a part of the same frame in which the spindle *v* has its bearing; they press upon the back of the rack, and keep it at all times in accurate contact with the pinion. A similar roller is applied at the back of the rods Q Q; by this means the teeth of the rack always engage those of the pinion, although they necessarily alter their direction at times by the change of position of the screw.

By this ingenious mechanism a circular saw will cut through a timber of nearly its own diameter, and with a rapidity that can never be attained by a reciprocating saw.

Machinery.

Manufactures.

cating motion: the saw when worn can be replaced by a new one, which practical defect being thus easily overcome, it possesses every advantage over the common reciprocating saw.

Other saws are employed in preparing the blocks, viz. a reciprocating saw for cutting up trees lengthwise, and circular sawing benches; these do not, however, differ from the mills we have described in the previous part of the article, and therefore do not require any further explanation.

In addition to the above sawing Machinery is that employed in preparing the *lignum vitæ* for the sheaves, which consists of two cross-cutting saws, one a reciprocating one, and the other a circular one. They do not differ in principle from those employed for the elm timber, although the hardness of the wood and different size of the timber require some alteration in the arrangement of the Machinery.

Reciprocating saw for cutting *lignum vitæ*.

(534.) The reciprocating saw is stretched in a wooden frame, which is necessary in consequence of the hardness of the wood requiring a much thinner blade and finer teeth than the elm.

The tree of *lignum vitæ* is placed horizontally, being held in a Machine which is similar to a large vice; it is opened and shut by two screws, both moved at the same time by cog wheels connecting them so as to move the jaws of the vice parallel. This Machine being used for cutting the ends of the trees into proper thicknesses for the sheaves, the vice which holds the tree is provided with a screw, which advances the whole together a proper quantity every time a sheave is cut off.

The vice is stationed upon proper sliders made truly parallel, in order that the pieces it cuts off may have parallel sides. This Machine is only used for converting the largest trees of *lignum vitæ*; the smaller trees are cut up by a circular saw, of very ingenious and curious construction.

Circular saw for cutting *lignum vitæ*.

(535.) It differs from the circular saw used for the elm, inasmuch as it can only be applied to the tree in one direction; but the tree is at the same time caused to revolve so as to present every part of its circumference to the action of the saw. The saw will therefore in this case also cut through a tree of nearly its own diameter. The construction is as follows.

The spindle of the circular saw is fitted in an iron frame which moves in a fixed vertical axis in the manner of a gate or door; its spindle being vertical the saw is of course horizontal, and its centre describes the arc of a circle when swung upon its centre of motion, but continues in the same plane. It is turned like the other Machines by an endless band which is conducted over pulleys, on an axle concentric with the axis of motion of the saw frame; by means of which the band has the same degree of tension at all positions of the saw: the vertical axle of the saw frame is supported by an iron standard, which is attached to vertical iron columns extending from the floor to the ceiling of the room. The tree of *lignum vitæ*, which is previously cut into lengths of two, or two and a half feet, is fixed in a chuck or clamp at the top of a vertical spindle, which is fitted in a socket in the middle of a cross bar sliding between two vertical columns. This cross bar is connected with another, which also slides up between two vertical columns, and they thus, together, form a large frame, which rises and falls by means of a screw working in a nut formed in the upper cross bar. The lower end of the screw rests on a step in the middle

of a fixed cross bar extending across from one column to the other, and perforated with two holes for the iron rods forming the two sides of the frame to pass through as they rise and fall. The chuck at the top of the spindle has two jaws by which it will hold trees of different dimensions, which are so contrived as to keep the tree at all times nearly central with the vertical axle. A rotary motion is communicated to the vertical spindle by a cog wheel fitted in a socket made in an iron plate, which is the base of the two columns. The lower end of the vertical spindle is made square, and moves up and down in a square hole in the centre of the wheel, and by this means the spindle continues to rotate whatever may be the elevation of the chuck.

When a piece of wood is required to be cut, it is fixed at the top of the vertical spindle, and raised by turning the great screw to such a height that the saw is opposite that part of the tree which is intended to be divided: the saw is in constant rotation from the mill and the workman presses it by a lever attached to the saw frame against the wood, which it cuts very rapidly. At the same time he turns the vertical spindle with the wood round by the winch, which operates on the cog wheel, so that all parts of the circumference of the tree are applied in succession to the action of the saw, which by this means will cut through a tree nearly twice its own radius, and in consequence of its revolution in a perfect plane, will cut off every piece of an equal thickness throughout. When the piece is thus separated, the workman swings the saw out of the way of the wood, and turns the screw by the cross handle, to raise up the frame with the spindle and tree the proper quantity to cut off such a thickness as will form the sheave intended. This quantity is measured by the screw, which has a ratchet wheel upon it with a click to prevent it from running back, which the weight of the iron frame and spindle would otherwise force it to do. The workman counts the number of teeth which pass the click as a measure of the proper elevation of the wood; in this way the operation proceeds with great rapidity, until the piece of timber is completely cut up, when the workman relieves the click, and the saw runs back and lets down the chuck ready to receive another length of tree.

For the above description of the saw-mills used in the manufacture of blocks, we are much indebted to Mr. Farey's description in Rees's *Cyclopædia*; but that account includes only those which are employed in cutting up the timber in proper sizes ready to be submitted to the block Machinery. We have, therefore, omitted here to describe the trepan, or crown saw, which is used to form the *lignum vitæ*, when cut into flat pieces by the Machine above described, into a circular figure, in order to form the pulley: this Machine belongs to the particular manufacture of blocks, and found described under that head.

(536.) *Saws for cutting piles under water.*—Foundations under water are generally formed in this Country by the use of a coffer dam, which consists of several rows of piles driven round the spot where the building is intended to be erected, with clay or other matter impervious to water filled in between them. The water may then be pumped out from the interior, which leaves the ground dry for the operations of building.

When the erection is completed, it of course becomes necessary to remove the coffer dam, which may be done either by drawing the piles or by cutting them off under water; the former is sometimes considered dangerous to the foundation by loosening the earth in the neighbour-

Machinery

Saws for cutting off piles under water.

Manufac-
tures.

hood, and the latter, although the most expensive method, is obliged to be resorted to.

The Machine employed for this purpose is required to give the saw three motions: the first by which it descends below the level of the water at the same time preserving the blade of the saw in a horizontal position; the second a horizontal motion in the direction of the length of the saw; and the third a horizontal movement in the direction of the breadth of the saw, which enables it to follow its work as it advances into the pile.

This is effected by two platforms; one of which is made movable by rollers on a framework attached to the top of the piles, where the workmen stand employed in working the saw; the other one is placed below this, and attached to it by four rods with racks and pinions, by means of which it can be raised or depressed according to the depth below the level of the water the pile is required to be cut off. The saw is fixed to a carriage which is movable on the lower platform, on rollers in the direction of the breadth of the saw; a rack is attached to the carriage which engages a pinion, working in the lower platform; by this means the carriage and saw is pressed forward against the pile.

The operation of the Machine is thus. After having fixed the two platforms horizontally, and the lower one at the required elevation, a horizontal motion is given to the saw in the direction of its length by four men upon the upper platform which causes it to cut into the timber; at the same time a man on the lower platform causes the saw to follow up its work by the rack and pinion above described, until the upper part of the pile is separated, when the Machine is moved into a new position to repeat the same operation on another pile.

A certain number of piles which cannot be cut must of course be left standing to support the Machine. These, however, need be very few, and may be drawn without risking the safety of the foundation.

The above Machine is principally used on the Continent, where caissons are employed in forming foundations under water. The caisson is a large pontoon or boat, the bottom of which is horizontal, and composed of beams well braced together. The sides are made of timber, calked so as to be perfectly water tight, and constructed in such a manner that they can be detached from the bottom when required. The caisson is placed over the spot where the erection is to be made, and built inside with masonry until it sinks, which it does on the top of piles previously driven and cut off, so that their tops preserve a perfectly horizontal plane. The sides of the caisson are then removed, leaving a thickness of masonry on the piles. In the same manner other thicknesses are added, until the masonry reaches the water's edge, when of course the building is carried on after the usual manner employed in other erections.

(537.) *Saws for cutting stone.*—These saws differ from those used in cutting wood in having no teeth upon them. Their action is therefore not that of cutting the stone, but the separation of the particles of the material they act upon by friction. Their effect is much increased by the addition of sand and water, which softens the stone and causes the particles to separate much more readily. The saw used in the common operation of sawing stone consists of a flat blade of iron fastened in a rectangular wooden frame, the saw forming the lower side of the rectangle. It is worked by a man who sits at one end, and gives a horizontal reciprocating motion by alternately pushing it from him and pulling it towards him.

When large slabs are required to be cut, the work is generally performed by two men, who sit one at each end of the stone. A board is placed so as to slope towards the fissure made by the saw, at the upper part of which a vessel of water is placed, which keeps a continual supply of water running down the board into the opening. A quantity of sand previously washed is also placed on the board at a little distance from the point at which the water is running, a portion of which the workman, by means of a stick with a hook at the end, pulls forward into the running water, which carries it down gradually into the fissure made by the saw.

The quality of the sand is varied according to the nature and hardness of the stone to be cut. For hard stone the sand is required to be very fine, but for soft stone, such as some kinds of Portland and Bath stone, the work is executed much more quickly by coarse sharp sand. The sand is required to be well cleaned, so as to be free from all extraneous matter, and sifted so that none of the particles exceed a certain size, which, as before observed, are varied according to the nature of the stone. That the sand should be perfectly clean is a matter which is required particularly to be attended to; for if a small piece of wood, or a grain so large that it will not penetrate but rolls over the stone, gets among the sand, the action of the saw is at once destroyed, and such an impediment when once got into the fissure made by the saw is very difficult to remove.

This method of cutting stone by hand is attended with a vast consumption of labour, as a good workman cannot cut through above twenty-five or thirty feet section of Portland stone in a day.

The work is besides very imperfectly executed, there being few workmen who can cut a slab which will not deviate considerably from the plane: an extra degree of labour and loss of material is produced by this means. These disadvantages of cutting stone by hand have led to the employment of Machinery for this purpose; and a very extensive mill has latterly been erected in London, which is said to perform, from the greater pressure it exerts on the saws, as much work in seventy hours by one saw as a man will execute in six weeks, and so true that scarcely any dressing is afterwards required.

The saws are stretched in a strong frame which receives a horizontal reciprocating motion from the steam engine. Any number of saws can be stretched in the frame at a time, according to the number and thickness of the slabs the stone or marble is required to be cut into. They are, of course, stretched perfectly parallel to each other, and the motion of the frame is in a truly vertical plane. The work must necessarily be performed with more truth than can possibly be given by the hand of man, as any irregularity in the texture and hardness of the stone will lead the saw out of the plane, unless governed by a greater power than a man can exert.

(538.) *Marble-mill.*—A plan and elevation of a mill for sawing and polishing slabs of marble is given in pl. xliii. fig. 1 and 2. The same letters refer to both figures. A A are the main timbers of the floor of the mill, and B B the level of the ground-floor. C D E F is a wooden frame, which is suspended by rods G G to the main beams of the floor with proper bearings: so that a free, horizontal, reciprocating motion may be given to it. The saw frame is attached to a cast iron box, which is movable upon the vertical post C F. By this means a reciprocating motion given to the frame C D E F by

tures.

a crank α on the main shaft is communicated to the saws.

The saws are made of wrought iron, and otherwise resemble those used by the common stonecutters. The saw frame H H H H is constructed of wood, and of a rectangular figure: it has several links in the shape of a stirrup, which traverse upon the two ends, to which the saws are fixed by pins. This will be better understood from fig. 3, which is a saw shown separately: Z Z is the section of the frame, and C C the above-mentioned links, to which the saws are attached; they are tightened by means of screws $d d$, which work in the links and press against an iron plate on the end of the frame. In this way there can be fixed any number of saws, and at any distance apart, according to the number and thickness of the slabs required to be cut. K K, L L are four upright posts constituting a frame, in which are placed the blocks of marble to be sawed into slabs, which serves at the same time to guide the frame of the saws. At each end there are a number of square, upright bars of iron, between which the saws pass; these bars serve to guide the saws in a truly vertical direction, and thereby insure an equal thickness in the slabs. The posts L L can be adjusted so as to make the frame of any required length for receiving different sized blocks. The cast iron box M, to which the saw frame is attached, is, as before observed, made to slide on the upright post C F of the vibrating frame C D E F. It is suspended by a rope, which goes over a pulley c , and is counterbalanced by the weight w . By this means the saws may be made to press upon their work with any degree of force. This sliding part is necessary to cause a rectilinear motion of the saws, because it is evident that the movable frame, from its pendulous motion, does not move in a straight line but in a curve. The pipe $e e$ serves to convey a supply of water to the saws while cutting; $f f$ is a small reservoir of water, supported by the frame K K, L L, which is kept constantly supplied from the pipe $e e$; $g g$ is an inclined board, also attached to the frame K K, L L, upon which is laid the sand used for cutting. The water from the reservoir $f f$ is constantly dripping upon the sand, and carries down a portion with it to supply the saw.

The slabs of marble, when separated, are removed to the other end of the mill to be polished, which operation is also here carried on by Machinery. The slab is placed on a carriage N N, which receives a lateral reciprocating motion from the Machinery, while the polisher has a longitudinal motion: in this way every part of the surface of the slab is acted upon equally. The carriage N N is supported upon rollers which run upon railways $h h$, fixed to the cross beams $i i$; j is a toothed wheel made to revolve by an endless screw on the main shaft, upon the spindle of which is a crank, which puts in motion by another crank l the toothed wheel n . The crank l can be adjusted to any length, but is at all times longer than the crank upon the spindle of the toothed wheel j ; by this means the wheel will not describe an entire revolution, but merely vibrate through an arc: o is a rack attached to a part of the carriage N N, which is engaged by the wheel n . It will thus be readily seen that the wheel n will give the carriage N N a lateral, reciprocating motion, which may be varied in extent, by the adjustable crank l , according to the dimensions of the slabs required to be polished. The polisher is put in motion by an upright frame O O, which vibrates with

the saw frame by the same crank upon the main shaft. The slab receives a continual supply of water from a reservoir Q Q, which is kept full from the feed pipe $e e$, while the workman adds the substance employed in polishing, which is varied in different parts of the process, and according to the nature of the marble.

(539.) *Polishing marble.*—The first substance should be the sharpest sand, so as to cut as fast as possible, which is to be continued until the surface becomes perfectly flat. After this the surface is rubbed with a finer sand, and frequently with a third. The next substance after the finest sand is emery of different degrees of fineness. This is followed by red powder called *tripoli*, which owes its cutting quality to the oxide of iron which it contains. Common iron stone, powdered and levigated, answers the purpose very well. Both of these give a tolerably good polish, which is however not considered sufficient, and the process is completed by a substance termed putty, which is an oxide of tin.

In the first process, which is merely that of reducing the inequalities of the surface, a variety in the size of the grains of sand is not a matter of any consequence; but in the subsequent processes a perfectly uniform quality of the sand is of the utmost importance, as if there are any particles larger or harder than the rest, the surface will be liable to be scratched so deeply as not to be removed by the emery. In order to get the sand of uniform quality it should be levigated and washed: the hard particles may in this way generally be separated, as they are generally of a different specific gravity from the rest. In the first process, the rubber or polish made use of is always made of iron, and, in fact, in all those where sand is employed iron is generally preferred. For the emery a plate of an alloy of lead and tin is used; and for the last process the rubbers consist of coarse linen cloths, such as hop-bagging wedged tightly into an iron plane. In all these processes a constant supply of small quantities of water is absolutely necessary.

Round articles of spar, gypsum, and marble are turned in the lathe with pointed instruments of steel: the pieces to be turned are attached to a wooden chuck by means of cement. Gypsum is very soft, and turned with great facility. Fluor spar and marble require the tool to be very hard, while the part to be turned requires a constant supply of water, which drops from a vessel above. After the articles are turned into the given shape, they are dressed with sand and emery, and afterwards polished with tripoli and putty.

Small specimens for collections of marbles are generally polished upon a lap, which runs in a lathe. These laps, however, ought to run with the axle perpendicular to the horizon, the face of the lap being truly flat and horizontal. The lap used for the first process should be of iron; the second of an alloy of lead and tin; and the third, which is for polishing, should be of iron with pitch. By means of some auxiliary Machinery, a number of pieces might be polished in this way at once, which would save much manual labour. Small pieces of marble may also be polished on the large Machine by cementing them with plaster on the surface of a large slab. By being placed on the same lever the large rubber sweeps them all at once.

(540.) We add here a short description of a marble-mill, in the neighbourhood of Kilkenny, which is remarkable for the simplicity of its construction and for the power which it exerts. One wheel, ten feet diameter, with twelve floats, gives motion by a crank at one end of its axle to a frame

Machinery.

Substance
employed
in polishing
marble.

Manufac-
tures.

containing twelve saws, which do the work of about twenty men. By a crank at the other end it moves a frame of five polishers, which do the work of about ten men. At this end Mr. Colliss, the inventor of the Machine, fitted a frame beneath the polishers with eight saws, and has found the power of the mill fully adequate to give them motion; so that the mill altogether may be fairly said to do the work of forty-two men daily. The saws are made of soft iron, and last about a week; they are constantly supplied with water and sand: the latter is taken out of the bed of the Nore, and washed till nothing remains but very fine and pure silicious particles. The marble taken from the mill is first polished with stone called *cove stone*, which is a brown sandstone, imported from Chester, which takes its name from being used in chimney coves. It is afterwards polished by a hone-stone, which is a piece of smooth nodule of the argillaceous iron ore, found in the hills between Kilkenny and Freshford. It receives its last polish in the mill with rags and putty.

Sawing
stone cylin-
ders.

In sawing stone for cylindrical pillars different Machinery is of course required. We have already given in sect. 341 a description of a method of boring stone pipes, which may be applied perfectly well to this purpose; but the Machinery commonly made use of differs considerably from it, and we therefore add the following description. When a complete cylindrical pillar is to be cut out of a block of stone, it is first necessary to fix upon the position of the axis of the cylinder, and then to lay the block in such a position that the axis may be parallel to the horizon. A cylindrical hole, from one to three inches in diameter, is bored entirely through the axis, and an iron bar, whose diameter is rather less than that of the tube, is put in it, so as to have sufficient room to slide freely as occasion may require. Each end of the bar should terminate in a screw on which a nut and frame may be fastened; the nut frame should carry thin flat pieces of wood or iron, each having a slit running along its middle, nearly from one end to the other, and a screw and handle must be adapted to each slit: by these means the framework at each end of the bars may be readily adjusted so as to form isosceles or equilateral triangles: the iron bar will form two corresponding angles of these triangles, the saw to be used two other corresponding angles; and another box of iron, or of wood, the two remaining angles to give sufficient strength to the whole frame. This construction, it is obvious, will enable the workman to place the saw at any proposed distance from the hole drilled through the middle of the block, and then, by giving an alternating motion to the saw frame, the cylinder may at length be cut from the block as required. This method was first described in the Collection of Machines approved by the Paris Academy.

If it is required to saw a conic frustrum from such a block, the two frames of wood must be fixed to those parallel ends of the block which are intended to coincide with the bases of the frustrum, circular grooves being previously cut in these frames to correspond with the circumferences of the two ends; the saw being worked in these grooves, will manifestly cut the conic surface from the block.

The best method of drilling a hole through the middle of the cylinder is thus. On a carriage running upon four low wheels, let two vertical pieces (each having a hole large enough to admit of the borer playing freely) be fixed two or three feet asunder, and so contrived

that the pieces and holes to receive the borer may be raised or lowered at pleasure; while the borer is prevented from sliding backwards and forwards by pieces upon its bar, which are larger than the holes in the vertical pieces, and which, as the borer revolves, press against them. A part of the boring bar between the two vertical pieces is square, and a grooved wheel with a square hole of a suitable size is placed upon it, so that a rotation may be given to the bar by an endless band which passes over the wheel, and another of larger diameter in the same plane, the latter wheel being turned by a winch handle in the usual way.

Machinery.

Snuff and Tobacco-mills.

(541.) *History of tobacco.*—Snuff and tobacco-mills are Machines employed in manufacturing the tobacco plant to the form in which it is used for smoking, for chewing, or for snuff. But before we enter upon a description of these processes, it will be interesting to take a rapid sketch of the history and the introduction of tobacco into this and other European Countries, in most of which, but particularly in England, it contributes very largely to the revenue. During the War, the Income Tax of this Country was considered, as it really was, a heavy and oppressive impost, while the tax on tobacco, drawn generally from the lower classes of Society for the indulgence of an artificially acquired taste, amounts to nearly one-quarter of the same sum, and it is paid without a murmur.

Discovery
of tobacco.

A branch of commerce thus bringing to the Revenue £3,000,000 sterling per annum, depending upon the consumption of an article, always repugnant to the natural taste, and at all times obnoxious to more than half the community from which it is raised, is a remarkable fact in political economy; and the general use of this herb amongst nearly all the Nations of the Earth, both civilized and savage, is not less so; and as such, a few particulars of its first introduction, its culture, and manufacture, will not, we presume, be unacceptable to the reader.

The first discovery of the properties of the tobacco plant, and its first application to the purposes of smoking, are entirely unknown, as the Europeans were not acquainted with it until the discovery of America by the Spaniards, where it had for some time been made use of by the natives.

The Americans of the Continent call it *petum*, and those of the Islands *yoli*. The Spaniards, who gave it the name of tobacco, took it from Tobaco, a Province of Yucatan, where they first found it and first learned its use: it is stated by others to have derived its name from the Island of Tobago.

The French at its first introduction among them gave it various names: as Nicotiana, or the Ambassador's herb, from John Nicot, then Ambassador of Francis XI. of Portugal, who brought home some with him to Lisbon, and presented it to the Grand Prior of the House of Lorraine, and to Queen Caroline de Medicis, whence it was also called Queen's herb, and Grand Prior's herb.

The first English settlement in America was made by Sir Walter Raleigh, who having, in the year 1585, raised a considerable subscription in London for the purpose, obtained from Queen Elizabeth a Charter for that purpose; and having sent two vessels to Virginia, they returned with reports highly favourable to the Country, bringing home with them pearls and tobacco.

Attempt at
making a
settlement
in America
by Sir Wal-
ter Raleigh.

This attempt was followed by another in the next year under Sir Richard Granville, who attempted to

Manufac-
tures.

settle a colony at the entrance of Roanoke river, in North Carolina; but these settlers were much harassed by the Indian natives; and being unable to maintain their ground, the remainder of them were taken up by Sir Francis Drake, and brought back again to England.

Mr. Lane, one of the Virginian adventurers, is said by some to have been the first person who brought tobacco to England; and Anderson, who has written very ably on the history of tobacco, seems to think that it might have taken its name at that time from Tobago. When we consider, however, the periods at which this Island was first discovered, settled, and populated, this conjecture does not seem probable.

In the same year, Sir Walter Raleigh fitted out two small vessels for America at Plymouth; and in the succeeding year, 1587, he fitted out three ships with one hundred and fifty persons of both sexes, who settled at Roanoke, where they found the second Colony had been destroyed by the natives: and these in their turn, being left three years unassisted, removed to Croatan, where they were supposed to have perished in like manner.

Captain Gosnol made a voyage in the year 1602, which was the first in sixteen years which had been attempted after Sir Walter Raleigh's failures; and he is said to be the first Englishman who ventured a direct route across the Atlantic Ocean, making discoveries upon the coasts commonly called New England; and although he appears to have trafficked with the Indians successfully, we have no account of his finding tobacco in these latitudes.

First per-
manent
settlement
made.

From the repeated favourable reports of Captain Gosnol and all others who had been in America, King James was induced to grant two Charters to distinct Companies, by the names of the London Adventurers and the Plymouth Adventurers. Ships were fitted out by these Companies, and the first permanent settlements were now made; but we do not at this period find any return in tobacco. The Company of London Adventurers obtained a confirmation of their Charter by the name of the Treasurer and Company of Adventurers and Planters of the City of London for the first Colony of Virginia, in the year 1610, being the seventh year of King James I. In 1618, the Colony of Virginia was found to increase, and considerable quantities of tobacco were cultivated, which at that time began to be much used in England.

History of
tobacco in
the reign of
King
James.

In 1620, King James, whose great dislike to tobacco seems to be amply recorded, issued a Proclamation which forbade the tobacco planters of Virginia from making above one hundred weight of tobacco per man. He also forbade any person to import into England any tobacco from beyond sea, unless authorized by a patent, upon pain of forfeiting the said tobacco.

The settlements in Virginia now began, however, to make rapid progress, one thousand three hundred persons being sent thither by the Virginia Company, together with suitable necessaries for the use of the Colony: but quarrels with the Indians brought on an unfortunate massacre of four hundred persons. This did not, however, affect the increase of the Colony; plantations were laid out, a well-regulated Country began to make its appearance, and Religion flourished. King James, however, still continued his opposition to the culture of tobacco; and made great exertions in the next year, 1622, to encourage the culture of mulberry trees and the propagation of silk-worms. The Virginia Company had by this year, 1626, raised a capital of

£200,000; but disagreeing amongst themselves, many selling out their shares, and others emigrating to Virginia with their families and servants, King Charles, who then reigned, considered it proper to take the business into his own hands, and to establish a Royal Government. This measure seems to have given a tone to the Government of Virginia; and from the encouragement given by this Monarch, by granting lands upon the easy terms of two shillings per annum quit-rent, payable to the Crown for each hundred acres, many respectable families were induced to emigrate to that Country.

Machinery

In 1633, the Colony of Maryland was established by Lord Baltimore, who carried two hundred persons to the new Settlement. It soon flourished and produced nearly as much tobacco as Virginia. The tobacco they produced is called Oroonoko, which, although not approved of generally by the English, was preferred by all the Northern nations.

Colony of
Maryland
established
by Lord
Baltimore.

About the middle of this century, tobacco seems to have grown into much greater esteem than formerly in England; considerable quantities were planted in several Counties, which thrived exceedingly well; but as this not only lessened the duty on the importation of tobacco, but likewise greatly obstructed the sale of that commodity from the Colonies of Virginia, which had cost so much expense in planting them, the loud complaints of the planters occasioned an Act of the Rump Parliament, in the year 1652, absolutely prohibiting the planting of any in England. Cromwell and his Council, in the year 1654, accordingly appointed Commissioners for strictly putting this Act into execution, but tobacco, notwithstanding, continued to be grown in considerable quantities.

Until the reign of James II. it appears that tobacco had been taxed only under the general name of poundage, but Parliament then stepped forward and granted a tax upon tobacco nominally; so that, by this law, Government drew an increase of revenue from this resource, over and above the demand of one shilling in the pound, or five per cent. poundage.

These proceedings of the year 1685 seem to be every thing that occurred which affected the commerce of tobacco materially during the reign of this Monarch. But the Revocation of the Edict of Nantes by the French King, brought on an emigration, which, under the patronage of the Crown, proved of material consequence to Virginia and the tobacco trade.

The Revocation of the Edict of Nantes occasioned a number of French families to take refuge under the protection of the Crown of England; and King William having offered them his patronage, and granted them lands in Virginia in 1690, a settlement was formed by them at the Manakin towns, formerly occupied by the aborigines of the soil, and one of the most fertile and eligible tracts of country in all America. It is situated on the South bank of James River, a few miles above the Falls, and must have proved a strong barrier against Indian encroachments upon the English settlements, as well as the means of affording considerable supplies.

In this same year, 1690, the Governor of New York, in alliance with the Irroquois Indians, made an attempt upon Quebec.

The commerce in tobacco from this time until the American War gradually increased. In the year 1772 the tobacco which was imported from Virginia and

Manufac-
tures.

Maryland into Great Britain was 54,915,282 pounds into England, and 42,883,981 pounds into Scotland; making a total importation for that year of 97,799,263 pounds; and the exportations for the same year were from England 7458 pounds, none having been exported from Scotland: the British consumption, confined to this year, must therefore have been 97,791,805 pounds.

The imports of tobacco into Great Britain in 1773 were 100,472,007 pounds; 55,928,957 pounds were imported to England, and the remainder 44,543,050 to Scotland. The exports for this year were 50,386,925 pounds from England, and 46,389,518 pounds from Scotland, making a total export of 96,776,443 pounds; so that the consumption of Great Britain for the year 1773 may be reckoned at 3,695,564 pounds of tobacco, although the exports from Scotland exceeded her imports.

The importation for the next year, 1774, was into England 56,048,957 pounds, into Scotland 41,397,252 pounds, making a total importation into Great Britain of 97,397,252 pounds. The exportation from Great Britain for this same year was from England 44,819,851 pounds, and from Scotland 33,857,064 pounds, making a total exportation from Great Britain of 78,676,915 pounds; so that the home consumption for this year may be estimated at 18,698,337 pounds of tobacco.

As this was the last year of a good understanding between Great Britain and her Colonies, it is not to be wondered at if irregularities should be found to follow this period of disquiet, until the contending claims were adjusted by an acknowledged right of jurisdiction, in which both parties discovered their true interest. The tobacco trade, however, seems to have strove hard to avoid a part in these political disagreements; for however far these contentions might have advanced, or however greatly the non-remittance of the American trade may have been inveighed against by popular pretensions, the public records show, even in 1775, when hostilities had commenced, that the importations did not diminish, until impeded by bloodshed and confusion.

In 1775, a Bill received the Royal assent, which went to restrain and limit the trade of these two Colonies (in common with the rest) to Great Britain and Ireland, and the West Indian Islands.

A Bill was in like manner passed in the same year to prohibit all trade with the American Colonies, then in actual Rebellion, during the continuation thereof.

This Act necessarily operated to interdict the whole commerce of tobacco between Great Britain and America; and after various clamours from those concerned, and a partial injury to the British revenue, it was judged expedient to repeal such of the several Acts of Parliament as prohibited the growth and produce of tobacco in Ireland, and to permit the importation of tobacco of the growth and produce of that Kingdom into Great Britain.

Such were the results of that interruption to the regular channel of commerce, which is always inseparable from the violent agitations of any momentous revolution in the system of national jurisprudence; but although War, or legal restraint, may for a while avert the accustomed course of commerce, Nature is ever struggling to reclaim her pre-eminence when the impediments of disorganization shall be removed. Of this position the American Revolution affords a very striking example; for, although the regular channel of the tobacco trade was obstructed, yet we find a portion of it surmounting this difficulty through the whole revolutionary period, by some means or other, and the balance returning to Britain among the blessings of Peace.

(542.) The two following Tables will exhibit this progress more particularly, and show in some degree the relations which subsisted between the prospect of conciliation and the prosperity of commerce.

An Account of Tobacco imported into England, exported thence, and consumed at Home during a Period of Ten Years, from 1773 to 1783, including the American War.

Years.	Pounds weight imported.	Pounds weight exported.	Pounds weight consumed.
1773	55,928,957	50,386,925	Exports exceed. Ditto.
1774	56,048,393	44,819,851	
1775	55,965,463	43,880,865	
1776	7,275,037	16,521,412	
1777	2,146,051	2,905,406	
1778	9,077,153	2,068,175	
1779	14,017,431	3,704,436	
1780	12,299,172	2,823,005	
1781	11,386,725	3,950,815	
1782	7,203,262	2,529,146	
Total	231,347,644	173,590,036	57,757,608

The years 1776 and 1777 show a greater exportation than importation by a balance of 10,005,730 pounds; consequently, it would seem as if so much tobacco must either have been cultivated in England during these two years, smuggled into that Kingdom, or exported out of old stock on hand, which might have failed of the usual annual consumption through the turbulency of the times.

The following is a similar Table exhibiting the quantity of tobacco imported into Scotland, exported thence, and consumed at home during the same period of ten years, from 1773 to 1783.

Years.	Imported.		Exported.		Consumed.
	Manufactured.	Unmanufactured.	Manufactured.	Unmanufactured.	
1773	0	44,543,050	41,783	46,347,735	Exports exceed. Ditto. Ditto. 4,618,090
1774	30	41,348,295	62,742	33,794,322	
1775	9	45,863,154	95,352	30,228,949	
1776	100	7,423,363	234,216	23,467,160	
1777	267	294,896	109,009	5,406,668	
1778	6	2,884,374	77,986	2,296,622	
1779	12	3,138,464	128,923	2,339,649	
1780	157	5,125,638	102,304	3,024,867

Act to en-
courage the
growth of
tobacco in
Scotland.

Here, as the exportations for 1773, 1776, and 1777 very far exceed the importations for those years, the presumption is suggested in like manner as in the case of England, that a portion must either have been home produce, smuggled, or remaining part of the old stock through an interruption of the usual consumption.

In 1782, an Act was passed to explain an Act made in the twelfth year of King Charles, (which was a confirmation of the Act passed by the Rump Parliament, entitled "An Act for prohibiting the Planting, Setting, or Sowing of Tobacco in England or Ireland,") and to permit the use and removal of tobacco, the growth of Scotland, into England for a limited time, under certain restrictions.

By this law, the recited Act was extended to Scotland: a report was to be made to the collector and comptroller of his Majesty's Customs for Scotland of all tobacco either in possession, being the actual growth of that Country, or being then actually growing; and the like duties were imposed which had theretofore been laid upon American tobacco: such tobacco was prohibited from removal into England by land, but was permitted to be conveyed thither by water under certain restrictions, the hogsheads being marked on the outside with the words Scots Tobacco.

A penalty was annexed to the crime of altering the legal marks and certificates; and tobacco removed otherwise than duly entered, marked, and certified according to the Act, together with the cattle and carriages which were used for its conveyance, became forfeited.

Duties were also to be paid upon this tobacco without any discount; the produce of these duties were to be substituted in lieu of the suspended duties upon American tobacco; nor was any drawback to be allowed on exportation.

Under this Act, the people of Scotland were encouraged in the experiments of planting tobacco; but through various causes, this project seems to have failed of success, and the succeeding Parliament thought it advisable to pass a law by which fourpence per pound was allowed to the planter for all such tobacco as, on account

of its inferior qualities or other defect, was insufficient to support the payment of the duties.

In 1783, the American War having terminated, the serious attention of the British nation became engaged to repair the damages which an injured revenue had received from an unprofitable suspension of trade.

The consequence was an immediate increase in the quantity of tobacco imported and exported, as will be seen from the following Table, which shows the actual importations from the year 1783 to 1799.

Years.	Quantity of tobacco imported.	Years.	Quantity of tobacco imported.
1783	19,579,581	1791	54,517,738
1784	43,492,302	1792	44,057,916
1785	43,255,741	1793	24,957,034
1786	45,379,795	1794	33,070,076

The difference of the amounts imported in the different years is considered by some to be owing to the effect of a fluctuating market; but if this had been the case, we should have discovered an excess of importation in some one year or other; instead of which there seems to be grounds to suspect that the depredations of French privateering had been more successful than was generally imagined; and that the tobacco trade increased in the last year in consequence of the success of our navy.

From the above period until the present time no material variation has taken place either in the laws and regulations relating to tobacco, or the quantities exported and imported. In the years 1823, 1825, 1826, some reductions were made in the duties, which has considerably increased the importation of foreign manufactured tobacco.

The amount and effect of these changes will be seen by the following Table.

(543.) *An Account of the Quantity of Tobacco imported and exported from the United Kingdom and cleared for Consumption, together with the Rates of Duty, and Net Amount of Revenue in each Year, commencing 5th January, from 1820 to 1831, both inclusive.*

Culture of Tobacco.

Culture of tobacco.

(544.) The spots generally chosen as best suited for the growth of the tobacco plant are recently cleared lands of the best possible light black soil, situated as near to a small stream of water as they can conveniently be found, due attention being also paid to the dryness of the place. The beds or patches, as they are called, differ in size, from a small salad bed to a quarter of an acre, according to the magnitude of the crop proposed. The lands are prepared for receiving the seed in March and the early part of April, as the season suits, first by burning upon them large heaps of brushwood, straw, or other rubbish, and afterwards by digging and raking them, in the same manner as ground is usually prepared for lettuce seed, which is generally sown mixed with the tobacco seed, and which answers the double purpose of feeding the labourer and of protecting the young tobacco plant from the fly, for which purpose a border of mustard is also found an effectual remedy, as the fly prefers mustard to any other young plant.

Cutting the crop.

When the crop is sufficiently ripe to proceed to cutting, which is known by the leaves changing to a yellowish-green colour with a certain mellow appearance and protrusion of the web of the leaf, the operation is assigned to the best and most judicious hands employed in the culture. They are each provided with a strong, sharp knife, with which they cut near the ground such plants as they judge to be ripe. The plants which have thick stalks or stems are sliced down the middle of the stem, in order to admit a more free and equal circulation of air through the parts during the process of curing, and to free the plant as far as possible from such partial retention of moisture as might have a tendency to ferment and damage the staple. The plants are then laid down upon the hill where they grew, with the points of the leaves all projecting the same way, as nearly as possible, so that when the sun has had sufficient effect to render them pliable, they may more easily and uniformly be gathered into turns or bundles by the labourers who follow the cutters.

Gathering the crop.

In preparing for gathering the crop of tobacco, it is

customary to erect a kind of scaffold in various places of the tobacco ground which may happen to offer a convenient situation. This is done by lodging one end of several strong poles upon any log or fence, and resting the other end of such poles upon a transverse pole supported by forks at about five feet from the ground.

In forming this part of the scaffold in the manner of joists, the poles are placed about four feet asunder from centre to centre, so that when the sticks which sustain the tobacco plants are prepared, they may fill the space advantageously, leaving but little room upon the scaffold.

The tobacco sticks, which are formed of timber, split, in the manner of laths, into pieces of four feet in length, and about one inch and a half in diameter, are laid upon the scaffolding in order to form a platform, upon which the tobacco is laid until in a sufficiently pliable state, and otherwise in a condition to be conveyed to the tobacco house, where it is suspended that the air may pass through it in the process of curing.

The barn which is appropriated to the use of receiving and curing this crop, is generally erected by the side of each respective piece of tobacco ground, or sometimes in the woods, upon some hill or particular site which may be convenient to more than one field of tobacco.

The plants are hung upon the tobacco sticks with the points downwards, the upper part resting upon the stem of the lowest leaf, or by the split made in the stem, when that happens to be divided. In this operation, particular care must be taken to allow sufficient space between each of the successive plants for the due circulation of air. About four or five inches is the general distance, but it is varied according to the bulk of the plant. From what has been said of hanging the plants, it will be perceived that the air is the principal agent in the operation of curing, and, in fact, in many cases the only agent; but when too much moisture is discovered, it is tempered by the help of smoke from small smothered fires made of oak bark kindled upon various parts of the floor where they may seem to be most needed. In this operation it is necessary that a careful hand should be always near; for the fires must not be permitted to blaze and burn furiously, which would not only endanger the house, but

Manufac-
tures.

by occasioning a sudden overheat while the leaf is in a moist condition, do great injury to the tobacco.

When the plants have remained suspended until sufficiently cured, they are taken down one by one respectively, and the leaves being stripped from the stalk of the plant, are rolled round the butt or thick end of the leaf with one of the smallest leaves as a bandage, and thus made up into little bundles to be laid in the casks.

The proper length of time during which the operation of curing should be continued is a matter upon which the success of the crop greatly depends, and can only be judged of safely by long experience and attention, and frequent handling, as tobacco often changes its quality with the change of the weather in a very short space of time. The method commonly employed of trying it is by stretching the leaf gently over the ends of the fingers and knuckles, and if it is in good condition, it will exhibit an elastic capacity, stretching like leather, and shining with a kind of moist gloss. It must be neither so dry as to break, nor so moist as to endanger the future rotting of the leaf.

When all the small bundles are made up, they are generally stowed in bulk upon pieces of timber forming a kind of platform upon the ground, having their points all laid the same way. In this condition they go through a sweat; and, therefore, care should be taken to examine them frequently that this operation of nature may be assisted by such regulations, in respect to air, heat, and cold, &c., as circumstances and experience may dictate. They must remain in this state until the fermentation shall have so far subsided as to promise a state of permanency in the juices, so that the leaf will bear a kind of elastic extension upon the fingers, similar to what has been before described, and at the same time so clear of moisture as to obviate any doubt of the risk of moulding in the passage across the Atlantic Ocean.

Where the malady of the *feu* or other disease has affected any of the plants during the growth, as to make it doubtful whether it is safe to pack them with the stem, in consequence of the liability of the latter to decay, the stem is separated from the leaf; which operation is called *stemming*, and is performed by taking the leaf in one hand, and the end of the stem in the other, in such a way as to cleave it with the grain. When the web is thus separated from the stem, it is made up into bundles in the same way as the leaf. Formerly the stems were generally thrown away, or burned with the refuse tobacco for the purpose of soap ashes, until the introduction of snuff-mills found a more economical use for them.

The tobacco is then ready to be sent to the market, and is packed in hogsheads, regulated by law to the standard of four feet six inches in length, in the manner in which it arrives in this Country. It is generally pressed down, that the size of the article may be reduced in stowage, which at the same time makes it less liable to exterior injury. This operation, however, requires some caution, as should it be bruised by this mechanical action, it is rendered liable to ferment and rot in its passage across the Atlantic Ocean, which effect occurs to such extent that a furnace is almost constantly employed at the London Docks to burn tobacco injured from this and other causes.

Snuff-mills.

(545.) Snuff-mills are employed to reduce the stems and leaves of tobacco to a powder, in order to form the article of commerce termed snuff. They are, like most other mills, constructed in various ways; the hand-mills very much resemble the common coffee-mill, but when on a large scale and the power of water, steam, &c. is

made use of, the reduction of the material is accomplished generally by two processes, first by passing the tobacco under vertical running stones, and afterwards in pestles and mortars. In the old mills, the running stones are not commonly employed, the grinding processes being performed entirely by the pestles and mortars: it is, however, necessary in this case to cut the tobacco stalks into very small pieces, which is performed by an engine consisting of stampers or pestles with knives at their lower extremities. A barrel containing lifters is made to revolve by the Machinery immediately behind the stampers, so as to engage projecting pieces upon them, by which they are elevated, until, by the revolution of the barrel, the projecting pieces are disengaged from the lifters, when the stampers and knives fall with their own weight into a box containing the tobacco.

In order that the tobacco may be equally reduced in all parts, a horizontal reciprocating motion is given to this box by a crank put in motion from the main shaft, by means of which a different portion of tobacco is presented to the action of the knife every time it falls.

Fig. 1, plate xlv. is a representation of a mill on Pl. xlv. this construction. AA is the floor of the mill, on which Fig. 1, 2, &c. are situated the pestles and mortars BB, which are made of wood secured by iron hoops *a a*. CC is the main shaft of the mill by which motion is communicated from the water wheel, steam engine, or whatever first mover may be employed; on this shaft is situated the bevelled wheel DD, which puts in rotation by a similar bevelled wheel the vertical shaft FF. The vertical shaft has a bearing in a step *b*, fixed to strong wooden framework in the ground-floor of the mill, and in plumber blocks attached to the horizontal beams *c c*. At the upper part is fixed a toothed wheel GG, which puts in rotation by the wheels HH the spindles of the pestles. KK is the frame containing the pestles and knives to reduce the tobacco previous to its being ground in the mortars. The tobacco is situated in the box *d d*, and is reduced by the knives *e e e*, &c., which are caused to fall upon it very rapidly by a barrel situated behind, shown dotted in the figure. A horizontal shaft *h* is situated in a position at right angles to the main shaft, from which it receives motion by a bevelled wheel *f*; and on the same shaft is another bevelled wheel *g g*, which engages a wheel on the axle of the barrel and thus gives a rapid rotation to it. The box which contains the tobacco, as before observed, receives a slight horizontal motion from the Machinery, in order that all parts of the tobacco may be equally acted upon: this is effected by a toothed wheel *l l*, which is caused to rotate by a pinion situated on the shaft *h*; on the axle of this wheel is a crank which gives motion to the levers *m m*, and thus also a slow motion to the box *d d*. When the tobacco stalks are in this way reduced into sufficiently small portions, they are conveyed to the upper floor and passed through mortars, where any additional degree of fineness may be given to the snuff by the screws *n n*, which adjust the position of the pestles.

In the mills where running stones are employed, it is also necessary, as in the mill above described, that the stalks should be first cut into small pieces; but as it is not required to be reduced to so fine a state, this process is generally performed by manual labour, by means of an engine very much resembling the common hay cutting Machine.

The vertical runners are similar to those already described under the article Oil-mill, each runner being

Machinery.

Manufac-
tures.

Vertical
runners
employed
in snuff-
mills.

placed at a different distance from the centre of the vertical shaft in order that they may act upon a different part of the lower plate. In snuff-mills, it is, however, necessary, in consequence of the injury which the snuff sustains if too great weight or pressure is used, that a free motion in a vertical direction be given to the frame in which the stones revolve, so that in the event of the tobacco being in a heap, the stones rise in passing over it and do not exert any pressure beyond that of their own weight. A further reduction of this pressure is necessary with some kinds of tobacco, which is attained by a counterweight attached to a rope passing over a pulley on the vertical shaft. The action of this weight is of course a deduction from that of the stones, so that by adding to or subtracting from it, the pressure exerted by the stones may be adjusted to the kind of material required to be reduced.

In the same plate, fig. 2, is represented the Machinery connected with the pestles and mortars, where, as before stated, the snuff is reduced to a further state of fineness. A A is the wooden framework in which the mortars are placed; to this frame is attached the cast iron framework B B B B of the Machinery by which the pestles and mortars are put in motion; C C C, &c. are the mortars, which are made of the shape shown in the figure. The pestles D D D, by the revolution of the vertical shaft, roll upon the inclined surface of the mortar, by which the further reduction of the tobacco is effected. The pestles and mortars are generally made of iron, when of wood they are of a different construction, consisting of a cone working within a cone. The angle of the inner cone is made rather smaller than that of the exterior, so that the surfaces are more closely in contact in the apex than in the base; by this means the snuff is gradually reduced in fineness as it descends upon the surfaces of the cones until it arrives in the apex, where it passes out at an aperture into a vessel placed to receive it. Pestles and mortars constructed in this manner form a more important part in the grinding of tobacco than those of the description represented in the plate; the latter being employed simply to give an additional degree of fineness to some kinds of tobacco, the chief reduction of the material being performed by the vertical runners, while the former perform the entire grinding process; the variations in the degrees of fineness being effected by adjusting the cones by means of screws, so as to approach nearer or further from each other.

Referring again to plate xlv., fig. 2, E E is a horizontal shaft having bearing at a a a in plumber blocks bolted to the transverse framing b b b. It has attached to it the bevelled wheels F F F, which engage similar ones upon the vertical shafts G G G, by which motion is given to the pestles. The horizontal bevelled wheels H H H are made free to move vertically on the shafts C C C, so that they can be put in and out of gear by ropes attached to the levers c c c c, &c., whereby the workmen may remove or replenish the snuff in any of the mortars without interrupting the action of the other part of the Machinery.

(546.) In fig. 3, 4 of the plate is represented an engine for cutting tobacco for the purposes of smoking, which differs from that employed in the snuff-mills; the object of the former being to divide the tobacco into as many small fragments as possible, and of the latter to divide the leaf into parallel shreds of various degrees of thickness. It consists of a cast iron framework A A, bolted firmly to the main timbers of the floor B B, in the

Engine for
cutting
tobacco.

lower part of which are bearings to support the horizontal shaft C C, which gives motion to the cutter. The tobacco leaves, after the stalks or stems are carefully removed, are placed in square wooden frames, which, by being put one above the other, form a box into which the tobacco is pressed by means of screws. One of these frames or boxes is shown at a a in the figure; it is constructed of such exterior dimensions that it exactly fills up the space between the sides b b of the frame, while the interior is equal to the width of the cutter. The tobacco is confined in the box by a cast iron plate f f, which fits between the sides of the frame, and is pressed down by screws which work in wrought iron brackets or ears g g attached to the frame. The part of the plate which extends beyond the cutter consists simply of two ears of the width of the sides a a of the box; they are pressed down by the screw h, and consequently serve as an additional security to the steady motion of the box.

Machinery.

The cutter, or knife shown at F in the figure, is bolted to a crank or carriage D D, which has a bearing at one end on the spindle E, and at the other receives a vertical reciprocating motion from a crank upon the horizontal shaft C C.

The frame or box a a containing the tobacco is placed upon a board e e, which is moved gently forward by a carriage m, traversing upon a long horizontal screw l l, seen in fig. 4. It will thus be obvious that at every revolution of the main shaft a shred of tobacco will be cut off throughout the whole section of the box by the descent of the knife. The velocity of motion given to the screw l l is varied according to the degree of fineness to which the tobacco is intended to be cut. This is effected by different toothed wheels which fit upon the screw l l, for as the motion is given to the wheel G by the lever and crank H, it will be advanced one tooth at every descent of the knife, so that if the wheel be of larger diameter, and greater number of teeth, a great number of cuts will be made during one revolution of the wheel, and, consequently, a greater degree of fineness will be given to the tobacco.

The tobacco when it has passed through the engine is exposed to a gentle heat upon a stove, and the parts which have become caked and pressed together are pulled to pieces by a workman; it is then in the state in which it is sold for smoking.

(547.) The principal part of the great variety of the snuffs of commerce is produced from various compounds of the stalks of the tobacco leaf with a substance termed *returns*, which is a portion of the leaf divided so small by the tobacco engine as to be unfit for the purposes of smoking, of which substance a considerable quantity remains from each batch operated on by the engine. For some of the finer sort of snuffs the tobacco leaf itself is employed, as the operation of stoving, which it of course has to go through if operated upon by the engine, is found to injure the flavour when employed for snuff. The quantities of the ingredients in forming different snuffs, and even for forming the same, are so varied by different manufacturers, that it is impossible to give any definite proportions, which is partly owing to the character of the snuff being in some measure produced at the mill by sifting it at different states of the process. It may, however, be given as a general rule, that in whatever way it is prepared, the darker snuffs contain a larger quantity of leaf, while those of a lighter shade are chiefly composed of the stalk.

Variety of
snuffs.

Manufac-
tures.

In preparing a batch of snuff, the ingredients are first well mixed together, and placed in heaps to ferment, a process which generally begins to take place in a short time after the mixture is made, but much depends upon the state of the weather. Soon after the fermentation commences, the tobacco heats very rapidly, and must be immediately turned by a shovel or the whole would be very quickly spoiled; this, for a time, impedes the process of fermentation, but in a few hours afterwards the action again commences, and the tobacco must again be turned. Upon the manner of performing this operation, depends in a great measure the peculiar quality of the snuff; and it is, therefore, one which calls for the greatest attention of the manufacturer, the more particularly as the state and rapidity of fermentation is so much influenced by the weather.

Lundafoot
snuff.

The celebrated Lundafoot snuff derives its particular flavour, chiefly from having the fermentation carried to a very high pitch before the batch is turned; and it is said that its first discovery was owing to the neglect of the man attending upon the batches, and who, by getting drunk, made his master's fortune.

Another story also prevails with respect to the discovery of this snuff so much esteemed by inveterate snuff-takers, which attributes it to an accidental fire, which by scorching some hogsheads of tobacco, gave them a peculiar flavour when manufactured. This story is, however, evidently without foundation, as the snuff manufactured by Lundafoot still continues to retain a peculiar flavour which cannot be imitated by other manufacturers; a circumstance which is not likely to continue if the effect simply depended upon the degree of drying.

When the ingredients have been a sufficient length of time under the process of fermentation, they are taken to the snuff-mill to be reduced to the required degree of fineness. In some cases the whole batch is ground into one sort of snuff; but different degrees of quality and fineness may be produced from the same batch by sifting in different states of the grinding process. If it is required to have several sorts, the batch, after having been for some time exposed to the action of the pestles and mortars, is passed over a sieve to separate the finer portions. This first produce will be much darker than the two remaining, and will consist chiefly of the leaf, owing to the stalks being harder and not so readily acted upon by the pestles. The residue which does not pass through the sieve is again ground, and sifted to produce a lighter coloured snuff, and so on for a third or for any varieties that may be required.

(548.) There are, also, considerable varieties in the tobacco used for smoking, but the number is by no means so great as of snuffs; they chiefly depend upon the quality of the tobacco, while snuff, although, of course, depending in a great measure upon this circumstance, is more particularly indebted for its peculiar flavour to the processes of the manufacture. The greater part of smoking tobacco is of two kinds, *shag* and *returns*. Both are made from the same cask of tobacco, the lighter leaves being chosen for the returns, and the darker ones for the common tobacco. The only difference in the manner of preparing them being, that the former is slightly sprinkled with water previous to pressing, while the latter is dipped leaf by leaf into water so as to be thoroughly moistened. The remaining kinds of smoking tobacco owe their flavour entirely to the leaf they are made from, and generally bear the name of the Country from which the tobacco is exported.

Machinery.
Different
kinds of
tobacco.

Another form of smoking tobacco, which within a few years has become very common in England, is in Cigars. The duty on those of foreign manufacture is very high, and a great many are in consequence made in this Country, although their quality is said to be much inferior to those made abroad. We have not been able to obtain any precise account of the process employed, on account of the secrecy observed by the makers; but it is probable, whatever secret there may be in it, that it consists only in the preparation of the leaf, as the particular form given to the cigar is performed by hand, simply by rolling up the leaf.

The other processes employed in the manufacture of tobacco are so simple as scarcely to need description. The tobacco called pig-tail employed for chewing is made by a wheel similar to a rope-maker's which is turned by a boy. A table, or platform, is situated level with the centre of the wheel, at which the workman stands with an instrument consisting of a flat board with a handle to it, by which he keeps adding to the rope of tobacco until it is of sufficient thickness, when it is rolled up and pressed. The black colour is given to it in various ways, but generally by a solution of tobacco in water. Tobacco in other forms, *viz.* nigger head, &c., used for chewing, is not manufactured in this Country; and the duty upon foreign manufactured tobacco of this kind is so very high as almost to amount to a prohibition, so that its use is very limited. An imitation of this tobacco is made in England, and sold under the same name, but it is much inferior to the foreign.

MANUFACTURES.

PART II.

MECHANICAL PROCESSES AND MANUFACTURES.

Manufac-
tures.
Definitions,
&c.

(549.) We have endeavoured in the preceding Part to describe such Machines and Machinery only as could be understood, independently of any particular mechanical process or Manufacture, although from the nature of the subject we could not in all cases wholly complete the illustrations without reference to the nature of the work to be performed; these cases, however, are but few, so that we may consider the preceding Part as an illustration of the principles, construction, and general action of Machinery, and the present division of the Work as descriptive of the application of those principles to Mechanical Processes and Manufactures.

The term Manufacture, in its original signification, undoubtedly means a work performed by hand; whereas at present it almost signifies a work performed *without* hands. One would smile at hearing a shoemaker's or a tailor's workshop called a Manufactory, and yet it is strictly so according to the original meaning of the word; whereas a number of mechanical processes, depending entirely for their guidance on Machinery, and that Machinery driven by steam, is without scruple denominated a Manufactory, although, perhaps, not a hand is employed in making the article, but simply in feeding the fire-place and attending to the Engines or Machines. This, however, is of no other consequence than as it renders the application of the terms Manufacture and Manufactory somewhat arbitrary, and may furnish an apology to the reader if he find a few of the following articles arranged somewhat differently from his expectation. We shall, however, in this Part, as in the preceding, endeavour to classify the articles according to the common adoption of terms, rather than, by consulting the actual signification of the words, to place them in an order wholly at variance with the common language of practical Science. Some processes are generally spoken of under the denomination of works, as iron-works, copper-works, saltpetre-works, &c.; these will fall under the general head Works. Other operations are simply designated by naming the article made, as button-making, clock-making, &c.; these will be classed under the head Mechanical Processes and Manufactures, but divided into two classes, *i. e.* of metals and fibrous materials; and, lastly, such as do not fall properly under any of the preceding heads, will be described under the term Miscellaneous Mechanical Arts. But we have once more to observe, that if, after all, the reader should not find any article in that division of the Work in which he expects to find it, we must trouble him to consult the general index, in which every article will be found arranged in alphabetical order.

Works.

Works.

(550.) Under this term we shall describe those mechanical processes, Manufactures, &c. commonly spoken of under this denomination, as gas-works, water-works, iron-

works, &c.; but it is not thought necessary here to attend strictly to the alphabetical arrangement which has hitherto been followed. It is proposed rather to consult that order which will give the most satisfactory view, and show the dependence of one process on another, without reference to any other classification.

Mechanical
Processes.

Works employed in the Manufacture of Metals.

(551.) It would be highly interesting if we were able to precede our description of the different mechanical processes connected with the Manufacture of iron and other metals, by a history of their first discovery, and the modes of working them adopted by the Ancients; but these discoveries, except in a very few cases, of those which may be called new metals, are lost in the mazes of antiquity. Gold, silver, copper, iron, and even the compound metal brass, are spoken of as known in our most ancient histories, without any reference whatever to their Manufacture; consequently it must be in vain for us at this day to offer the least conjecture on this head. All that we can do is to state the progress of the Art, and the improvements that have taken place in it within a comparatively short period of time. In our Chapter on Mining, we have endeavoured to describe the means employed in this Country for obtaining the ores from the earth, and the further processes of stamping and pounding, in cases wherein those operations are adopted, so as to render them ready for the subsequent process of smelting, and for the Manufacture of them into bars or other forms fit for the working them into such shapes and forms, and for such purposes, as the present state of the Arts requires. We shall now, therefore, consider the ore as already obtained, and reduced to the state necessary for the subsequent stages of its Manufacture.

Iron-Works.

(552.) Iron in a malleable form has undoubtedly been known from the highest antiquity, although there is great reason to believe it was extremely scarce, and considered of great value, not like gold or silver for its beauty and purity, but from its actual uses to mankind. It is repeatedly spoken of by Moses in the *Pentateuch*, and by Homer in the *Iliad*; and that it was at that time considered of great worth, is proved by Achilles proposing a ball of iron as one of the prizes to be distributed to the victors at the Games instituted in honour of Patroclus. Indeed, the extreme difficulty of extricating the metal from the ore must in these ancient times have rendered it very scarce, and of course very valuable. Its high importance in the present day in its application to the Arts is too well known to require any remarks of ours on the subject; but it is very neatly pointed out by Fourcroy, who observes: "Without iron agriculture could not have existed, nor could the plough have rendered the earth

Manufac-
tures.

ferile. The philosopher, while he studies the progress of the human understanding, and compares the fortune and state of the different nations established on various portions of the surface of the Globe, will remark, that their iron-Works seem, in some measure, to be proportioned to their intelligence, to the advancement of reason amongst them, and the degree of perfection to which the Arts have arrived. When we consider it in this point of view, as the agent by which men, in the variety of its uses, and the numerous wants it supplies, acquire enjoyments which would be unknown to them if they did not possess these products of their industry, iron must singularly contribute to extend their ideas, to multiply their knowledge, and to conduct their spirit towards that perfectibility, which Nature has given no less as the character of the human species, than as the source of all the advantages it can enjoy."

Iron is a malleable and ductile metal, of a bluish-white colour, is susceptible of a very high polish, and of the specific gravity, variously stated, from 7.600 to 7.895.

General View of the Process of making Iron.

General
process
described.

(553.) There are several particulars connected with the conversion of iron ore to a metallic state, which require to be rather minutely described; but we think that these will be better understood by readers unacquainted with the subject, if we first, without attending to minutiae, describe generally the several steps of the process. We may then return and point out those peculiarities which require further illustration.

Roasting.

The first step to be taken after the ore has been obtained, is to submit it to a considerable degree of heat in a kiln, in order to drive off the water, carbonic acid, sulphur, and other ingredients which enter largely into the composition of the ore. This is technically called roasting or calcining, and in the process a loss of weight is sustained of from 20 to 30 per cent. The kiln is fed at the top, as the roasted ore is removed from the bottom, after having sustained the requisite degree of heat; and considerable skill is exercised in this first process; for if there be too much heat the pieces of ore, or, as it is called in Wales, the *mine*, will melt and adhere together; and if too little, they will contain a portion of water or sulphur, and are obliged to be thrown aside at the kiln as *raw* or *green mine*.

Smelting.

The next step in the process is to convert the calcined ore or mine to its first metallic state. This is effected in the blast furnace, in which proper proportional quantities of ore and coke are employed, with some other substance to act as a flux, the latter depending upon the nature of the ore; particulars of which will be described as we proceed. These materials are submitted to a strong blast, produced by some one of the powerful blowing Machines already described. (Art. 383.) As this process proceeds, the metal falls in a fluid state to a part at the bottom of the furnace called the *hearth*, which is of different dimensions in different Works; in some the quantity of fluid metal produced every twelve hours amounts to from four to six tons, and at these intervals it is generally run off, forming what is called *pig iron*.

Running off
the metal.

The method of running off may be thus described: a hole is already formed at the bottom of the hearth, which is stopped with a mixture of sand and clay during the smelting process; but when ready, the hearth is *tapped* by opening this aperture, and the metal of course issues. The stream of metal is received from this aper-

ture into a long channel formed in a sort of sand, and from this principal channel, which is called the *sow*, there proceed laterally a number of smaller channels, called *pigs*, of the well-known shape of pig iron. As the fluid proceeds down the central channel, the workman interrupts its progress every now and then by a long piece of wood, in order to cause the metal to flow into the lateral channels as it proceeds, as otherwise it would not retain sufficient fluidity to flow into these, so as to form each completely; but by stopping it as above described, the pigs are all perfectly formed in the order in which the metal flows. As soon as the metal is well set, the pigs are broken off from the central channel or *sow*, and the latter is also broken to pieces by the blows of a large sledge hammer. The quantity of metal thus obtained, compared with the quantity of roasted ore employed in its production, varies of course considerably with different ores, but the product may, at a mean estimate, be stated to amount to about 40 per cent. And we have seen that in the roasting a loss of weight has been sustained of from 20 to 30 per cent.; so that from the raw mine to the first state of pig iron, a loss is sustained of about 66 per cent., or, which is the same, it requires about three tons of raw mine to form one of pig iron.

The iron in this state of pigs is distinguished into six different kinds, depending on circumstances which will be described further on: of these, the first three, *viz.* numbers 1, 2, 3, are considered as foundry metal; they contain carbon in different degrees, but all of them in a higher degree than those selected for making the bar or malleable iron. We now proceed to describe the latter process.

(554.) Here the first step is *refining* the pig iron in the *refinery* or *run out* furnace. These are much less than the blast furnace, not being calculated to hold much above a ton. The pig iron being introduced into the refinery furnace, is kept in a state of fusion for about two hours, during which it parts with a quantity of its carbon and other impurities, and comes out, as the term implies, much more pure than in its former state.

The furnace, as we have seen, is tapped every two hours, the yield each time being about a ton; and the furnace being constantly worked by a double set of men, through day and night, ought to produce about seventy tons of metal per week; perhaps it may be considered to vary from sixty to seventy tons for each double furnace, that is to say a furnace of larger dimensions than those denominated single furnaces, and furnished with two blasts instead of one only. The iron, from the refinery furnace, is run into a long flat mould, varying of course in different Works, but commonly about twenty feet long and two feet broad: this is placed near the refinery furnace, and the metal, when the furnace is tapped, passes from the furnace to the mould, through a channel formed for the purpose. The mould is set over a cistern of cold water, to facilitate the process of cooling, and to cause the metal to set quickly, after which it is easily broken down by hammers to fit it for the next process. The loss of weight sustained in the refining amounts to about 10 per cent.; but it of course varies considerably under different circumstances. Taking, however, 10 per cent. as a medium, the proportional yield at this stage, compared with the quantity of raw mine, will be about 29 or 30 per cent.

(555.) The next process is what is technically called *puddling*, at a furnace called a *puddling* furnace, which will be described in a subsequent part of this article. It will be sufficient here to state, that about three or four hundred

Mechanical
Processes.

Refining

Puddling.

Manufac-
tures.

weight of the refined metal is introduced into the furnace, which in about half an hour begins to melt, and the puddler then commences his labour. The puddler's furnace, as will be seen in another page, more resembles an oven than a furnace, having a large iron door, through the opening to which the metal is introduced and removed, and through a small opening in the bottom of the door the process of puddling is carried on; this hole being only just large enough to receive the tool, and for the man to see his work. When the metal begins to melt, the puddler introduces an iron tool, something like a hoe, and with this turns the mass about, exposing the part not melted to the hotter parts of the furnace, and removing the melted part to the cooler, till the whole becomes fluid. He then, with his iron tool, stirs it about very diligently in all directions, exposing every part to the action of the flame; and he is obliged to be constantly changing his tool, which soon becomes red hot; it is then dipped into cold water, and he proceeds with another. During this process the liquid metal heaves and boils, giving off an elastic gas, and gradually becomes thicker and more stiff; he still, however, perseveres in stirring it as long as it will yield in this form to his tool, and even after it has assumed something like a soft or solid mass, he keeps it in constant motion: having, however, by this time divided it into about five or six separate balls, each of seventy or eighty pounds weight. In this state the workman says the iron is come to a *state of nature*, and here the puddler's labour ends. The iron is now in fact approaching its malleable state, and it only remains to give it form; in the course of which, what still is wanted to render it perfectly malleable is effected.

The balls being still at their full heat in the puddler's furnace, his *under hand* or assistant removes them with a heavy and powerful pair of tongs to an adjacent hammer, weighing about four or five tons, of the kind represented in fig. 2, plate xxxv. Here the iron receives a few heavy blows: this is called *shingling*; it makes the balls more solid, and reduces them to an oblong shape better calculated for going between the rolls; it also squeezes out a portion of the liquid cinder or oxide, which is separated from the pure iron in the puddling. Generally about twenty blows are sufficient for giving the *bloom*, as it is now called, its proper shape, provided it has been well puddled.

Shingling
and rolling.

(556.) While still hot, the bloom is transferred from the shingler to the rolling-mill, of which a description is given. (Art. 514.) It is first passed through the largest hole in the rolls, then through the next size, and so on in succession. It is received on the other side of the rolls by a boy, called a *catcher*, and handed back by him with a pair of tongs over the rolls to the roller, who, having reduced the size in one pair of rolls, passes it through different grooves in the second pair. In the latter, it is reduced to a more accurate form, and to the required width and thickness. During this process, as well as in the shingling, a portion of fluid cinder and oxide are pressed out, some flying off with violence; but the greater part falls into a hollow under the rolls, where it is afterwards gathered up and laid aside. During this process we may state, as a medium case, a further reduction in weight of about 10 per cent., which makes the yield of rough bar iron to the original raw mine as about 26 to 100; there having been a loss of weight from the first of 74 per cent.

Balling.

(557.) The next and final process is what is termed (although now according to the modern mode of working

improperly) the *balling* and final rolling. This is done by first cutting the rough bars into certain lengths, with a powerful pair of shears, of the kind described in Art. (449.); and in these lengths they are piled up into stacks by women and boys, called *plers*. The pile generally consists of five or six of these pieces, each two or three feet long, according to the nature of the finished bar required, and it is important that they should be laid as evenly as possible. The stack is now introduced into the balling furnace, which resembles in size and in most other particulars the puddling furnace; and here the mass is brought to a high welding heat, which requires, however, to be attended to with great care, and calls for considerable skill in the baller. Each pile, of which there may be ten or twelve, having attained the proper degree of heat, and being prepared to follow in proper succession, is in its turn transferred from the furnace to the rollers, and after passing backward and forward from one side of the rolls to the other, through holes of less and less capacity, the bar is produced complete, in a state fit for the use of the smith.

The loss of weight in the last process is about 10 or 11 per cent., which leaves a yield of about 23 or 24 tons of finished bar iron for every 100 tons of raw mine.

(558.) The reader will not of course understand these numbers to be given as the fixed and invariable result of the product of an iron Manufactory; the final quantity of finished iron obtained is liable to great variations according to the nature of the ore, and the manner and perfection of working; they are merely intended to give to a person wholly unacquainted with the subject a general idea of the yield that is obtained at a medium, and as such they are perhaps as nearly accurate as they could well be given. Neither must it be understood that the process, as above described, is that pursued in every iron-Work: in some cases the puddling is omitted, and in others the shingling; the iron in the latter case being passed immediately from the furnace to the rolls: there are also other varieties.

The methods we have described are those most commonly followed in Wales; but it may be well to point out one or two of the other methods here alluded to. Where the puddling is omitted, the iron is exposed to the heat of a charcoal fire, in a sort of furnace very similar to the refinery furnace, and it is continued in this situation until the metal is thought to be sufficiently decarbonized. It is very frequently stirred during the operation, and when brought to a *state of nature*, as we have before used the term, is collected into masses, and removed by tongs under a large hammer, denominated, as applied to this particular use, a *stamping hammer*, where it is beaten into cakes, which are afterwards broken up, and treated in the *balling furnace* as above described. This is the old mode of working, and the iron obtained by it is by many conceived to be of very superior quality. The heat produced is considerably inferior to that afforded by coke in the *run out furnace*; and the iron is less surrounded by the fuel than in the case just mentioned. The present charcoal fire is properly a *refinery*, and not the one which is used merely as a preliminary to the process of puddling. Here the business of decarbonization is at once completed; and the resulting metal is in the same state of purity as that yielded from the rollers, after it has been puddled by the other method. *Balling* and *blooming* followed in regular succession, and plates or bars were produced exactly as before.

According to the second mode of treatment, in which

Mechanical
Processes.

Other
modes of
Manufac-
ture de-
scribed.

Manufac-
tures.

blooming is omitted, the masses obtained from the *balling furnace* are reduced under the hammer into the form of solid, cubical blocks; and when their temperature is too much lowered to be capable of any further working, they are again heated in a fire called a *chafery*, which is urged by a powerful pair of bellows, and scarcely differs from a common smith's forge, except in being larger, and the coke upon it being heaped up to the unusual height of at least two feet. In this situation they are raised to the point of welding, and afterwards hammered out into ingots of a flattened shape. Iron bars are united to them very shortly after they are brought from the *balling furnace*, to afford a greater facility of management, in the same manner as in the making of *blooms*; and these, as before, are detached, when the ingot is sufficiently formed. The iron produced in this way is not considered so good as that afforded by either of the other processes, and is employed, for the most part, in the commonest services of the Arts. Repeated rolling or hammering is the only means of imparting the fibrous texture so necessary to good bar iron; and as this treatment is less frequent in this mode of operation, the deficiency of value in the materials obtained may very probably be referable almost exclusively to this circumstance.

The above include the whole of the important variations that are practised in the manufacture of bar iron. Other shades of disagreement may be traced in different Works; but they are of a nature too trifling and unimportant to merit any particular enumeration. The Art is still in its infancy; and the light of Chemical Science, by being brought to a focus here, cannot fail to disclose many improvements on the present mode of procedure, which will greatly abridge the expense now incident to this valuable branch of national industry.

Amount of
materials
employed
compared
with the
product.

(559.) The quantity of malleable iron produced, compared with the quantity of raw mine employed, we have seen amounts to about 23 or 24 per cent. at a medium. We may now state the quantity of coal employed. First, the coal is to be converted into coke, and in this process there is a waste of weight of about 33 per cent. or a product of 66 per cent.; and the quantity of coke and of roasted mine employed in the furnace are nearly equal; but more accurately the proportions may be stated as 100 coke to 96 roasted mine, or 66 coke to 64 roasted mine, or 100 coal to 80 raw mine, or to $26\frac{2}{3}$ pig iron, that is $3\frac{1}{3}$ tons of coals are consumed in the furnace, and 3 tons of raw mine to produce 1 ton of iron. It is also estimated that one ton of coal for every ton of iron is consumed in the kiln, and in the steam engines for the blast, and about one ton of limestone as a flux to each ton of iron. The actual weight of material consumed, therefore, in the production of a ton of pig iron may at a medium be stated as follows:

Raw mine	3 tons = 2.4 tons of roasted ore.
Coal for furnace $3\frac{1}{3}$ tons =	2.5 of coke.
Do. for kiln, &c. }	1 ton.
Engines.	
Flux.	
	—

$8\frac{1}{3}$ tons of materials for 1 ton pig iron.

This is the amount of materials requisite to produce a ton of pig iron, but we have seen that a reduction of weight takes place in converting the pig iron to the finished bar in the ratio of 33 to 24. To produce therefore a ton of finished bars, these materials must be

increased in the inverse proportion, or as 24 to 33, or in the ratio of 8 to 11. Hence to produce a ton of finished bar, there will be required

Coals for kiln, steam engine, and	} 6.53 tons

used in the production of one ton of finished bar.

We have thus brought under the notice of the reader in one condensed point of view the general process of an iron-Work, and a statement of the medium product of such a Work, or rather the quantity of material employed to produce a given quantity of iron in the form of both malleable and pig iron. We have before stated, that these proportions and product are by no means constant, but they may be taken as a pretty fair estimate, particularly of the Welsh iron-Works. It remains for us now to describe more particularly the nature of the different furnaces, and to enter more minutely into some of the processes hitherto but slightly alluded to, for the sake of giving the reader a concise and connected view of the operation from the beginning to the end.

(560.) *Roasting*.—This, as has been seen, is the first process, and requires but little description, although it is certain one in which considerable skill must be exercised; it is either done in kilns, or in heaps in the open air, in which alternate layers of coal and iron stone are laid on each other. These are exposed to the open air, and the mass is allowed to burn till the fire is exhausted. This process is necessary in consequence of the carbonic acid and clay, and other foreign bodies which enter largely into the composition of the ore. It is an important point to get rid of these impurities as completely as possible before the mine is used in the furnace. When this is done in kilns, the roasted ore is removed from the bottom and its place supplied above. The skill here required is in supplying a sufficient degree of heat to drive these impurities off as completely as possible without carrying the heating too far. If there be too much, the pieces of mine will be partially melted and adhere together, and if too little, some of the impurities of the ore will remain, and must be thrown aside by the *filler* into the kiln head, as raw or green mine.

Different
methods of
roasting.

(561.) *Making the coke*.—Before the coal can be employed in the blast furnace, it must be converted into coke, a substance of great importance in the manufacture of iron. There is a great difference of coal in different districts even in Wales, and a very different degree of the coking process is requisite accordingly. The method of coking in Wales, is not very economical.

The general system is to place the coal in long open heaps, containing 30 or 40 tons, laying the pieces of coal as loose and open as possible, to allow of their swelling, and covering the whole with smaller pieces so as to give the external surface a tolerably level appearance. The heap is then set on fire in different places, and suffered to burn till the whole surface is completely ignited. When this is the case, the coker covers it entirely over with the dust and ashes of former fires, to exclude the air and prevent waste, and it is left to burn out, or

Manufac-
tures.

rather to cool gradually, till it is in a proper state to be uncovered and carried to the tunnel head of the furnace.

The cooling is generally, however, expedited by pouring water upon the cokes before they are uncovered. This is sometimes done to a great extent, and is found to improve the quality of the coke, by making it harder, and expelling more of the sulphur of the coal than would be got rid of without the application of water.

By the system of open fires, much of the coal must be reduced to ashes before the air is excluded. This is more particularly the case when the wind is high, as it not unfrequently is in those mountainous and exposed situations. On a stormy night, the unremitting exertions of a double set of cokers are perhaps required on the coke hearth to keep the fires tolerably covered; and in an extensive Work, probably sixty or a hundred tons of coal may be wasted in one night in spite of all their labour.

The coke hearth of an iron-Work in full operation, presents a grand and imposing spectacle in a dark night. The long rows of flame produced by the burning of many hundred tons of coal, extended over a vast space of ground, and flickering in the wind, the black, grotesque figures of the cokers brandishing their long rakes, and partially visible through the thick lurid smoke, with the roaring of the blast and the noise of Machinery, seem to realize the descriptions of the infernal regions by Virgil or Dante, rather than any thing familiar to our experience in this habitable world.

The writer of this Essay was so fortunate as to arrive on the hills about Merthyr, on a fine summer's evening just after dark, and the scene which presented itself to his view, he will always remember as one of the most extraordinary he ever witnessed.

The coals in Monmouthshire, which are very bituminous, require from five to nine days to become thoroughly coked, while those about Merthyr take only about half or less than half that time. The coal when coked, has parted with all its moisture, tar, and hydrogen gas, and a great part of its sulphur; and according to its properties, is either of a dull jet black, with the appearance of charcoal, or exhibits a bright metallic or vitreous lustre, with a porous texture. The more carbonaceous matter it contains, the better; and those beds of coal are therefore the most esteemed which present in the fracture the dull, soft appearance of carbonized vegetable matter. Small pieces of coke may be occasionally selected of such a quality that they can hardly be discriminated from charcoal, having that fibrous texture and peculiarity of lustre by which it is characterised. Coke, indeed, may be considered only as a substitute for charcoal in the smelting of iron, and was formerly unknown as applicable to this purpose. Charcoal is at present in general use in Russia and Sweden, and indeed is used at a few Works in this Country. The iron produced from it is particularly calculated for conversion into steel; but its high price and insufficient quantity would totally preclude its general use, even were it a much greater desideratum than it is. The impurities of the coke of South Wales, or, in other words, the ashes that are left after combustion, are a very important subject for the investigation of the iron-master. They are of many different kinds, some of which are much more prejudicial to the working of the furnace than others; and the strata of coal in which these prevail the most should therefore be avoided altogether, or used with caution, mixed with other qualities of coal. If the coke, after combustion, leaves a

red ash or residuum, sulphuret of iron is indicated, the sulphur of which produces a positively bad effect on the quality of the iron smelted in the furnace. If the ashes are white, they probably contain magnesia, silice, or alumine, either singly or combined; but the two latter of these earths are only detrimental as so much extraneous matter: indeed, each, singly, may be of service as a flux, according to the nature of the iron-stone with which it comes in contact; but magnesia is injurious, as it produces an opposite effect in rendering the flux less fusible by combining with it.

(562.) *Blast furnace.*—Blast furnaces, like all the other parts and processes of iron-Works, differ very considerably in different districts, as well also in the same district in different Works. Generally, however, we may state the Welsh blast furnaces, which are amongst the largest, to consist of a square mass of masonry, with a base of from thirty to fifty feet, gradually diminishing towards the upper part to about twenty or twenty-five, and about forty or forty-five feet in height, with a roof extending from one or more sides to shelter the workmen, and to keep the cast house dry. There is also a covered communication between the top of the square masonry and the high ground at the back for the purpose of supplying the materials. The cylinder at top called the tunnel-head, is furnished with doors or openings, through which the materials are introduced to the furnace: one is seen in fig. 2. This is made of fire-brick hooped together with iron, and is about eight feet in diameter. The masonry of the whole furnace is also strongly bound together with iron ties and stays. There are arches in the centre of the four sides forming recesses in the solid masonry; the one in front to enable the men to work the furnace and run out the iron, and those at the other sides for the more convenient introduction of the blast; the blast pipes are shown in the plan, fig. 3. The blast which enters at C, fig. 1, 3, produces the greatest heat, a little above this point where the iron and the cinder are melted, and where the former drops into the cavity D, called the *hearth*; this and the part immediately above, called the *boshes*, which are from fourteen to seventeen feet in diameter, are generally made of large pieces of coarse grit or pudding-stone, carefully jointed with fire-clay, so as to resist as much as possible the intense heat to which they are exposed. Recently, however, some hearths have been constructed of fire-bricks, which are much cheaper if they will but last sufficiently long.

The black parts which are shown on the walls in fig. 1, 2, are vent flues for the escape of moisture which could not escape from such a massy building without injuring the walls when the heat is applied to the interior: *d* is the dam stone over which the melted cinder flows while the metal is retained on the hearth, till it is tapped at a hole on a level with its bottom, and *T*, which forms a bridge over this passage, is called the *tymp stone*. The part between E and A is called the *cementing part*, and contains the ore and coke mixed together, which are acted upon just as they would be in a close vessel; that is, the oxygen of the ore combines with the carbon of the coke, forming carbonic acid, or rather perhaps carbonic oxide, which is generally the case at this temperature. This change will go on, in each of the masses of ore, to the very centre, where it consists of metallic iron and earthy matter only. As soon as the oxygen is separated from the iron, the combination of carbon with the metal commences, and continues till, from the reduction of the mass below, it is in its turn brought to the melting

Mechanical
Processes.

Blasting
furnace de-
scribed.
Pl. xlv.
Fig. 1, 2, 3.

Manufac-
tures.

point when the lime combines with the earthy part of the ore, and the liquid metal falls down. The vitreous cinder, thus separated, also becomes iron, and, being specifically lighter than the liquid iron, floats on its surface.

The melted iron occupies the part D, fig. 1, 2, in the furnace, and the cinder floats above it, till it runs off over the *dam stone*, as above stated; and the metal itself ultimately would run over the same, but, previously to this, it is let out at the tap hole, which is on a level with the bottom of the cavity which contains the iron.

The quality of the metal, with respect to its quantity of carbon, will depend upon the quantity and quality of the coke with which the ore has been surrounded in the cemented part. The appearance of the metal when it flows from the furnace will indicate when the coke has been used in excess. A substance floats upon the surface of the metal, which, when cold, has a shining appearance resembling plumbago, and is known to the workman by the name of *kish*. The presence of this substance shows that the metal is saturated with carbon; since it is found to consist principally of carbonaceous matter. If it is produced in any considerable quantity, it gives the iron-master a hint to increase the burden of his furnace, by increasing the proportion of ore.

The appearance of the cinder is, also, a good criterion for showing the working order of the furnace, as well as the quality of the iron. When the ore is not sufficiently cemented, unchanged oxide, in some cases, and the defect of carbon allow a considerable quantity of the oxide of iron to incorporate with the cinder, by which it assumes a greenish-yellow colour, which is not so favourable an appearance as the blue tint, or when it has the least colour.

In some instances, when the furnace is in very bad condition, the cinder becomes of so dark a green as to appear almost black: this arises from a great excess of oxide of iron which has escaped reduction in the furnace. This cinder is very fusible, from the presence of the oxide, and is considered a very unfavourable appearance. The cinder which has the least colour soon becomes solid after it flows from the furnace, from its containing less of the oxide of iron. This shows that the cementing process is carried on to a proper extent, by which the oxide has been converted into carburetted iron, in which state it can no longer combine with the earthy matter, and deserts it when the cemented masses are melted by the action of the blast. The blue tint in the cinder, which, in some instances, is almost as vivid as ultramarine, generally accompanies the ore, and owes its colour, in all probability, to an oxide of iron, containing less oxygen than the black oxide. This may throw some light upon the mystery of the black and red oxide of iron being combined with quantities of oxygen, which are as 2 to 3, indicating the existence of a third oxide, which, in all probability, is that to which the cinder owes its blue colour. This idea is strengthened by the fact, that it is never produced but when there is the least oxide of iron in the rest of the cinder. Much light may be thrown on the subject of iron smelting, by a series of well-directed experiments upon different proportions of the earths; but previously to such a course, it might be advisable to make a correct analysis of the best cinder, which is that freest from colour, and which at the same time fuses with the least heat.

(563.) We now come to the application of the blast. In fig. 3 are shown two blast pipes; there are sometimes three, and frequently but one. These holes, through which the blast passes, are called in Wales *twyeres*, and the general practice in that Country is to blow with three, or at least to have three, although frequently only two are used, and occasionally only one. The management of the *twyeres* requires considerable skill and practice, and the profitable working of a furnace depends very much upon the way in which this part of the business is conducted. The form of the orifice or *twyere* through which the blast is admitted to the furnace does not always assume the same aspect. The constant rushing in of the stream of cold air chills the part of the melting metal to which it is opposed on its entrance to the furnace, and produces a sort of artificial pipe or channel extending more or less into the interior. It is a rude perforated cone adhering by its base to the side of the interior of the furnace and stretching its apex horizontally towards the centre, and the different appearances which it exhibits indicate the manner in which the furnace is working, and are the signals to the workman who has charge of it to make the necessary changes in the proportion of the materials or the application of the blast: sometimes the *twyeres* will become so strong and project so far as to meet together in the middle of the furnace; when this is the case, the progress of the blast is of course much obstructed; at others, the *twyere* will drop off close to the side, which is as prejudicial as the other extreme. All these variations are met or prevented by a careful *keeper*, as this workman is called, who watches every indication of change, and takes his measures according to the emergency of the case. Sometimes he will stop one *twyere* entirely, and provide for the admission of the same blast to the furnace by increasing the size of the remaining blast pipes; at other times he will increase or diminish the total quantity of blast, or he will alter the proportions of the materials at the tunnel head. With all these precautions, he is unable always to keep the furnace in the most advantageous state of working, and, what is more extraordinary, he is unable to account for the changes that frequently occur.

There is certainly much to be learned in the iron trade before we can boast of any thing like a complete knowledge of its different processes. We observe many facts in this as well as in other branches of the manufacture, of which the most that we can say is, that they are connected with or caused by certain other accompanying facts, though we are ignorant *how* this connection exists; often, indeed, our knowledge does not extend so far.

(564.) *Blast engine*.—We have now to consider the method of generating the requisite blasts, and the mode of equalizing and applying it. It is produced by powerful steam engines, with one or two exceptions, where a great local facility of water-power obviates the necessity of steam. Water, however, can be used only where it can be depended upon in a constant and ample stream even through a dry summer, as it is of the first importance that the blast of a furnace should not be withheld even for a few hours. Instances have been known of the whole contents of a furnace becoming one solid mass from having been cooled by the accidental stoppage of the blast.

We have already (under Art. 383.) described several Machines for this purpose; it will, therefore, be sufficient to state here, that commonly the blast

Mechanical
Processes.
Engine ap-
plication of
the blast.

Manufac-
tures.

engines employed in these kinds of work are supplied with a large cylinder at the opposite end of the beam to the steam cylinder, and of double its diameter; *i. e.* four times its area. The blowing piston, therefore, will produce a volume of air at each stroke of the engine equal to four times the contents of the steam cylinder; but at a pressure of only one-fourth of that on the steam piston by the joint action of the vacuum and the steam, friction deducted. Thus, suppose that an engine with a steam cylinder fifty-four inches diameter, and a pressure of five pounds per inch of steam, is supplied with a blowing cylinder of 108 inches diameter, it will be capable of keeping up a blast at a pressure of $2\frac{1}{2}$ pounds per square inch; for it is calculated that the pressure in the steam cylinder of such an engine, deducting the friction, is about 10 pounds per square inch. This pressure may be reduced at pleasure, by working the engine more slowly, or with a lower pressure of steam in the boilers.

If the volume of air thus generated were to be passed immediately through small pipes to the twyeres, it would produce an intermitting, irregular blast, almost dying away at the end of every stroke of the engine, and exerting its utmost force between the pauses. This would be very injurious to the furnace, for which great regularity in the blast is necessary. To obviate this inconvenience the air is passed from the engine into a large iron reservoir, called a regulator, from its effect in equalizing the current to the twyeres. The regulator is sometimes in the shape of a sphere, as already stated in the article referred to above, entirely closed up, with the exception of the passages for the ingress and egress of the air, and produces the required effect simply by the elasticity of the large volume of condensed air which it contains: it is then called a dry regulator. Sometimes it is in the shape of a cube or cylinder, open at the bottom, and fixed in a larger vessel or cistern of water. In this case it is called a water regulator, and the column of water at the sides keeps up the requisite pressure within; but there is an inconvenience attending this construction that is likely gradually to lead to its disuse. The introduction of moisture into a furnace with the blast has a bad effect, both on the working of the furnace and the quality of the iron produced; and it is found that the condensed air in the water regulator, exposed as it is to a large and constantly agitated surface of water, has the property of taking up a very considerable quantity of moisture in solution. This is particularly the case in summer, as the higher the temperature of the air the more moisture it is capable of dissolving. This circumstance accounts in part for the fact, that furnaces never work so advantageously in summer as in cool weather; so sensitive are they in this respect, that, after working extremely well for some time with a dry North or East wind, they will frequently change all at once when the wind veers to the West or South, with moisture or rain.

(565.) It was long thought that the disadvantage experienced in the summer months was to be attributed simply to the heat of the weather, and it was therefore thought that a cool blast was most favourable to the smelting of iron; whereas lately a patent has been taken out for heating the blast artificially before it is introduced into the furnace. Here, however, care is taken that with its increased temperature no moisture is absorbed, otherwise the effect would be injurious instead of advantageous.

Air cannot support combustion until heated to 1000° of Fahrenheit's thermometer, and therefore until it acquires that temperature, by being in contact with the heated mass, it must be acting prejudicially, and consequently the nearer it can be brought to that point before it enters the furnace the better. The heat proposed to be obtained by the patentee is about 300° of Fahrenheit. The diameter of the blast pipe at the twyeres is various, according to circumstances. With a strong pressure blast and three twyeres a diameter of three or four inches may be considered sufficient. The greater the quantity of blast introduced, the greater generally will be the quantity of iron produced, but the quality will be deteriorated. If foundery or melting iron be wanted, this must be of good quality, and the blast used must not be so great as when an inferior quality is wanted to be subsequently refined and manufactured into bar iron.

(566.) *Charge of the furnace.*—The charge of the furnace as to quantity varies of course with the magnitude of it. We have in the above description had in view generally one of the larger kind, and which we may suppose to be driving fifty charges a turn, with a burden of 6 hundred weight of roasted mine; this requires therefore 50×6 hundred weight = 15 tons of roasted ore produced from about 18 tons of raw mine. The quantity of metal run from such a furnace ought, according to the proportions we have before stated, to yield about 6 tons of pig iron every twelve hours: the quantity of coke will be about the same, that is, fifty charges at 6 hundred weight each, or 15 tons, to produce which $22\frac{1}{2}$ tons of coals will be required, and as the limestone runs about a ton for every ton of iron produced, this will be about 6 tons, so that the whole charge for the twelve hours is about 36 tons, or 72 tons for the twenty-four hours; but reckoning the weight of raw iron ore and coals originally employed for the coking, roasting, &c., the whole amount of materials consumed in such a furnace in twenty-four hours is 57 tons of coals, 36 of mine, and 12 of limestone, the production being only 12 tons of pig iron. We see, therefore, how providentially it has been contrived, that the coal and iron are found together; for were they deposited in distant Countries the expense of transfer would very much diminish the value of each material. The limestone is also generally near at hand, but this is of less consequence being used in much less quantities.

(567.) It has been seen, that such a furnace as we have been describing requires to be daily fed with more than 100 tons per day of raw material, and that at the utmost it yields only about 12 tons per day of pig iron; of course there must be in all such Works an immense accumulation of cinder. If we only reckon the quantity actually supplied to the furnace this amounts to 72 tons; and the product being 12, there must still remain a very great weight of cinder; but this weight is by no means equal to the difference between 72 and 12 tons, which would be 60 tons, but it is found that the total amount, including iron, cinder, and ashes, does not exceed 40 tons; so that 20 tons' weight has been carried off in the escape of oxygen, carbon, &c. This actual dissipation is very extraordinary, but the 40 tons remaining, or rather the 28 tons remaining, after deducting the iron, from each furnace per day, together with the cinder from the refinery and other furnaces, still leads to immense accumulations in a series of years, and they are in fact such as to give a peculiar aspect to all our iron districts.

(568.) The cinders from the forge and refinery are

known to contain still so much iron as to be richer than the ore employed; and some years back Messrs. Hill and Co., of the Plymouth Works, near Merthyr, obtained a patent for the use of these as a substitute for mine for the furnace. These materials are the scoria and dross produced in the different operations of the refinery and forge. It is an oxide of iron, with but little foreign matter, and therefore containing a great proportion of iron, frequently 60 or 70 per cent. It was supposed by the patentees not to have been used before for any purpose, although it was known to contain a large proportion of iron. The contrivance of Messrs. Hill and Co. consisted in mixing the cinder with argillaceous matter, so as to form a more complete imitation of the ore in its natural state. A portion of the shale or clunch, adhering to the natural ore when first raised, was to be put into the furnace with every charge of cinder. This of course made the combination less rich or more lean, as it is termed, and thereby prevented the injurious effect which had been observed in attempts made upon it without this precaution. The experiment succeeded, but the patent was invaded, and the actions brought against those who invaded it were successfully defended, a prior use of the same method having been proved. Since which, of course, every iron-master has it in his power to avail himself of the large store of these cinders, the accumulation, perhaps, of a long series of years. Many experiments were made, but the iron turned out very faulty and bad, and it is now pretty generally admitted, that although such cinder may certainly be used and rendered productive, it can only be done to a certain extent, and can be employed only with great care. The utmost, perhaps, that can be done in this way, with our present knowledge on the subject, is to work up in future all the cinder that is produced at the forges and refining, leaving the present accumulated heaps till some new discovery in the Art shall enable the masters to employ them in larger quantities: and this has been done, it is said, to a much greater extent in Staffordshire than in Wales. It is certainly much to be desired that such an experiment should succeed, and we should imagine the time will come when this material will be found much more valuable than it can now be considered; and that when Chemical Science has made further advances, a more effectual method will be discovered of separating the metal, which is known to exist in a very large proportion and combined with so few impurities. We must be content, however, to proceed gradually. When we look back to the process of manufacturing iron twenty years ago, we have every reason to be satisfied with the progress which has been made in the knowledge and improvement of the subject; and we may confidently anticipate that the next twenty years may be equally marked by advancement. It is true that many schemes projected by scientific and experienced men have failed; that many favourite speculations, which have appeared most plausible in the closet or laboratory, have been incapable of being followed up in practice on a large scale; but this want of success should by no means dishearten us: the very failures themselves lead us on to more accurate knowledge and correct results, and thus pave the way, slowly it is true, but surely also, to ultimate success and certainty.

Our present want of knowledge is remarkably displayed in the different operations of converting pig iron into malleable or wrought iron. Pig iron is commonly supposed to be a combination of the pure metal with carbon and oxygen; bar iron is the same metal freed

from these impurities. It is not ascertained in what proportions oxygen exists in the pig; but we know that the carbon is more abundant in proportion as the iron is soft and tough. Thus then we are struck with this apparent contradiction, that the purer the iron is in the state of pig, as far at least as carbon is concerned, and in that respect the more it resembles malleable iron in its Chemical properties, the more removed it becomes from it in its appearance and Mechanical properties; the white iron of the furnace being, as will be seen, the hardest and most brittle that can be produced. It is, however, so difficult to follow up Chemical analysis and to obtain results with minute accuracy, in a process requiring intense heat, that hitherto the phenomena attendant upon the refining of pig iron, and its conversion into bars, may be said rather to be guessed at than perfectly explained.

(569.) Before quitting this first stage in the manufacture of iron, it remains for us to speak more minutely than in the former general description of the nature and character of the iron as first obtained in the form of pig. It has already been stated, that the pig iron produced in the operation of smelting is of very various qualities, according to the purpose for which it is wanted, and the circumstances under which it is manufactured. It may be divided, first, into foundry iron and forge iron; the former being used in the state of pigs, for casting; the latter being only applicable to the manufacture of bar iron. The reason of this is, that, from its nature, it is too thick when melted to adapt itself to the shape of the mould, and, when cold, is too weak and brittle to be serviceable as cast iron, even if the other objection did not exist.

But the foundry iron comes first to be described. There are three qualities of it: first, second, and third.

No. 1 foundry iron differs in its Chemical composition from the other sorts, by containing more carbon. It is, indeed, combined with as much carbon as it is capable of holding; and to effect this combination in its full extent, the coke containing the fibrous appearance of charcoal, or the purest carbon, is selected. The tendency of this combination is to render the iron soft, and to make it very fluid when melted, so that it will run into the finest and most delicate mouldings. It is used for small and ornamental castings, and any thing that requires a minute and perfect adaptation to the shape of the mould. It is distinguished in its appearance by great smoothness on the face or surface of the pig; and in the fracture it exhibits a large, dark, bright, open grain, intermixed with dead spots of a lighter colour and closer texture. When broken, the pig does not ring, but sounds rather like lead, falling dull and dead upon the block over which it is broken. It is also so soft as to yield readily to the chisel. In running from the furnace, the surface of the melted metal is smooth and dull, breaking occasionally into streaks and cracks of a darker and brighter red. When it is highly carbonized, the pigs and the cinder are frequently covered with small bright black laminæ of a substance called kish. It is a pure carburet of iron, or black lead, and evinces an excess of carbon in the pig.

No. 2 foundry iron is less carbonized than No. 1; not so soft, closer grained, and more regular in the fracture, not so fluid when melted, nor so smooth on the face of the pig; it is, however, harder and stronger, and is preferred for all the less delicate parts of Machinery, where strength and durability are required.

Mechanical
Processes.

Nature and
qualities of
pig iron.

Manufac-
tures.

These two sorts are all that are recognised in some places as foundry iron. Their being combined with so large a dose of carbon and oxygen renders them unfit for manufacture into bars; but iron of the next quality, or No. 3, having less foreign admixture in its composition, is destined indifferently for the forge or the foundry. It is used extensively for castings where great strength is required, or in situations where it is to be exposed to constant wear and tear; such as tram plates, heavy shafts, and wheels, cylinders for steam engines, and many descriptions of heavy work. It is selected for these purposes from being still harder than No. 2, and possessing so great a degree of toughness as well as hardness as to make very strong and durable castings. In appearance it differs from No. 2, in the same way as that does from No. 1, being more closely grained and more regular, and darker when broken. From its appearance, it is often called dark grey iron; by which term it is, indeed, as well known as by that of No. 3.

The next quality, *bright* iron, is never called foundry iron, although used extensively for large castings. It possesses great strength and hardness, but not fluidity enough to adapt itself to intricate or minute mouldings. It derives its name from its appearance, which is of a lighter colour and brighter lustre than that which has hitherto been described.

Mottled iron is used exclusively for the purposes of the forge, as it is too thick and brittle for the foundry. It is smooth in the fracture, hardly exhibiting any grain, and appears to be compounded of two qualities imperfectly combined, being spotted or mottled with grey and white.

White iron is supposed to contain a very small portion of carbon, less than any other sort of pig iron. It is totally unfit for casting, and is sometimes so thick as hardly to run into the pig moulds, although they are purposely made very large; and so brittle, that the largest and most unwieldy pigs may be readily broken by a blow with a sledge hammer. It is too hard to yield in any degree to the chisel. The colour of the fracture is a silvery white, shining and smooth in its texture, with a foliated or crystallized structure.

Thus we have six distinct gradations of pig iron, produced under different circumstances in the blast furnace: No. 1 and No. 2 foundry, No. 3 foundry iron, No. 4 is also occasionally used as foundry, but No. 5 and No. 6 are exclusively employed for forming malleable iron.

(570.) *Refining furnace.*—We have seen that the first step after the pig iron has been obtained is refining, the mode of which has been slightly attended to. We shall now describe the furnace and process a little more at length. This furnace is shown in fig. 4, 5. A is the recess or trough made of cast metal, the bottom consisting of freestone or brick; it is surrounded on three sides with a cavity, through which water is continually passing from the cistern C: *pp* are two pipes from a blowing Machine, inserted into the conical openings, and kept cool by water from the pipe *s*, which runs off at the pipe *n*; these are to blow the fire, which occupies the recess A. The fire being made in the trough, and filled with coke, the pigs of iron are thrown into the midst of it, and coke heaped up around them, the blast being kept up, and the outsides of the trough being kept cool by water. The metal first melts, and the blast instantly acting upon it separates a quantity of its carbon, but not nearly to the extent to which it was carried in the old method already alluded to, (Art. 559.) the metal

still remaining liquid. In this state it receives the action of the blast for some hours: we have stated two hours as the usual time, but it is frequently exposed to it much longer. It is then run off at the bottom of the trough, through an opening O, as already described, into the mould or recess D E. A large quantity of the vitreous oxide of iron also runs out, which is formed by the blast and floats on the surface of the melted metal; indeed it is through the medium of this vitreous oxide that the metal below is deprived of its carbon. The blast first destroys a portion on the surface, and then oxidates the iron thus deprived of its carbon; this forms the vitreous oxide, which floats upon the carbonated mass. The oxygen, therefore, of the floating oxide is constantly in contact with the carbon of the metal below. The stratum immediately below gives its carbon to that deprived of its carbon above, and thus the change is effected to the bottom of the trough.

(571.) *Puddling furnace.*—It has been already stated that the next step is the puddling, and in fig. 6, 7 a furnace for this purpose is represented. In fig. 6, *a* is the grate, supplied with fire through an aperture in the side called the stoke-hole, and furnished with bars at the bottom for a proper supply of air, and for the escape of the ashes; *b* is the body of the furnace, where the refined metal is placed and exposed to the heat of the flames, which are drawn from the fire by the current of air over the little brickwork division between *a* and *b*, and are turned downwards again by the inclination of the roof, so as to curl and play upon the surface of the melted iron at *b*; they are then carried through the narrow part or neck of the furnace to the stack or chimney *c*. The chimney is carried up to the height of about thirty feet, and bound together at different points with iron, to keep it firmly together. There is a damper at the top of it, by which the puddler regulates the degree of draught (and consequently heat) to his furnace; for, during some parts of his operations, he wants a more intense heat than at others. The draught and heat of these furnaces are so great that the flame is carried completely through to the top of the stack, where it comes in contact with the damper, which is frequently nearly red hot. The bottom of the furnace *dd* was formerly always composed of sand, and occasionally is so still; but the most general plan is to construct it of a thick cast iron plate, which is preserved from fusion by a coat of the oxide of iron or cinder, which is formed in puddling. An artificial bottom is thus created, and found to answer better than one constructed upon sand.

Fig. 7 is an elevation of a puddling furnace, in which the whole side is of one or more plates of cast iron lined with brick, the two sides being connected by bars at the top over the brickwork of the roof: *a* is the stoke-hole, so contrived as to be stopped with a piece of coal, which is used to equalize the heat, by preventing the ingress of air to the furnace, except through the bars at the bottom; *b* is the door, raised when necessary by the lever and chain *d*; *c* is the stack, where a portion of the chain is shown by which the damper is raised or lowered. The furnace, when first lighted, requires three or four hours before it is ready to be charged, or to receive a heat of metal, as it is called; that is, the proper quantity of refined iron.

The first department at the forge is the weighing out of these charges, and delivering them at the puddling furnaces. The general weight of the charge is about 3½ hundred weight, or from that to 4 hundred weight; it

Mechanical

Manufactures.

cannot be stated with precision, as the practice varies at different Works.

The puddler being supplied with his charge, whatever it may be, of metal broken into fragments or convenient sized pieces, puts it into his furnace, closes the door, and waits its being ready, which it is frequently in half an hour. At the bottom of the door is a small hole *h*, which we have already mentioned as being only large enough for the puddler to introduce his tool, and to see his work. The first business is, so to dispose of his metal that those parts which are less exposed to the action of the flame may be drawn more immediately under its influence, so that the whole quantity may be brought to the same state, and melted as nearly as possible together, as has been already described.

In such a puddling furnace as that above described, some time is lost whenever fresh metal is introduced while it is acquiring sufficient heat, and this time cannot be well stated at less than twenty minutes or half an hour, while the whole operation does not require more than two hours; so that a large proportion of the time is thus wasted. To avoid this there have been several contrivances for heating the fresh charge of metal to a certain degree before it is introduced, and while the preceding heat is in progress. One plan is, to make the flue rather wider, so as to form a sort of recess for the reception of the fresh charge, which is placed there by the puddler's man through a small door for the purpose, without any interruption to him, and when his heat is finished it is drawn forward, and is ready for him to go on with without any delay. The simplest manner, however, is to make the body of the furnace longer than according to the usual construction, and to have a second door between that where the puddler works and the stack. This affords sufficient convenience and room for the succeeding charge of metal, which at the same time is so near the workman, that when he has completed the heat and sent the balls to the shingler, it can be instantly drawn to its place, and if put in at the right time is just in the proper state for working. With these furnaces nine heats can be worked by one man in twelve hours; and if, as is sometimes the case, the furnace is provided with three sets of men instead of two, each set working eight hours out of the twenty-four, instead of twelve, ten, or even eleven heats may be finished in the twelve hours; the additional number of turns being of course attended with a proportionate increase in the weight of the produce, without a corresponding consumption of fuel; it is therefore very recommendable for its economy.

From the puddling furnace the blooms or puddlers' balls are transferred by the puddlers under hand to the shingling hammer, and thence to the puddle rolls, where the iron is converted into rough bars. These two steps require no further illustration beyond what has been given in the general description, and only a few lines more of explanation are necessary to be added relative to the balling furnace, and final operation of forming the finished bars.

Balling furnace

(572.) *Balling furnace*.—We have already said that this so much resembles the puddling furnace as to require no distinct figure to represent it, the principal difference being, that instead of the solid iron bottom, with the protecting coat of cinder, it is of loose sand, renewed from time to time as it becomes uneven or wears away. In other respects it is like the former, a reverberating furnace heated by a coal fire at the end, the flame of

which is drawn on by the current of air, and turned down in its course to the flue by the inclination of the interior of the roof. Mechanical Processes.

The further process of cutting and piling the rough bars, as also the balling and rolling, will be sufficiently understood by referring to the general description in the leading part of this Essay, and by consulting the article Shears and Rolling-mill in our preceding division.

(573.) *Remanufacture of old iron*.—Before we quit this subject entirely, it is proposed to say a few words on the subject of the remanufacturing of old iron, which is then called faggoted iron, which is generally considered to be superior in toughness and strength to new iron. The principal manufacture of this kind in the neighbourhood of the metropolis is at Messrs. Howard and Co., King and Queen Iron-Works, Rotherhithe; although we believe it is common in all large smitheries to have a pair or two of rolls, and a furnace for re-forming worn-out or fragments of iron. There is a convenience of this sort in the smithery in the Dock-yard at Woolwich, and we believe also in most other large establishments of this kind. Manufacture of faggoted iron.

In the process as we have seen it at Messrs. Howard and Co.'s the smallest piece of iron, such as old horse-shoes, horse-nails, &c., are piled together by boys and women in old or waste pieces of new, thin plate-iron doubled up in the form and size of a medium tea-caddy, and bound up in that form by waste hoop-iron. In this form they are introduced into the furnace, and when sufficiently heated are run backward and forward through the rolls into small bars, hoop-iron, &c., which is considered not only equal in quality but superior to the best new iron. We have been much indebted in the above article to H. Jones, Esq., and to an ingenious Treatise on Iron by the Society for the Diffusion of Useful Knowledge.

Steel.

(574.) It has been observed that the history of the discovery, and the first modes of working iron, are lost in the mazes of antiquity. The discovery of steel is certainly much more recent, but still we have not been able to find any account of its first introduction, nor indeed is the distinction between iron and steel, notwithstanding the present advanced state of Chemistry, very clearly understood; we know only, that steel is a particular modification of iron, and that it is a compound of carbon and iron in an intermediate state between that of malleable and pig iron; but in what respect the dose of carbon it receives makes such a marked difference in the character of the two materials is certainly not well understood. Pure iron, indeed, is considered to be wholly divested of carbon; but it is not likely that such a piece of iron was ever produced, so that all malleable iron in some measure partakes of the property of steel, and it was probably some accidental circumstance which first led to a peculiar character being observed in iron made in a particular way. This first marked the distinction, and afterwards the term steel was used to denote the different quality; for there can be no doubt that the difference between the two was known before the cause of the distinct character was so well understood as it is at present, although we have still much to learn on the subject. Steel.

Dr. Ure, in his *Chemical Dictionary*, defines steel of. Description of.

Manufac-
tures.

simply as a modification of iron, and concerning which, he observes, our knowledge is not very precise, notwithstanding the researches of many celebrated Chemists. The increase in weight which the bars of iron receive in their conversion into steel, he states, on the authority of the proprietor of the Monkland Iron-Works, to be from four to twelve ounces per hundred weight; but this proportion does not agree with other estimates: the first proportion constituting mild and the latter very hard steel. Should the process be pushed much further than this, the steel would melt, and in the act of fusion would take an additional dose of carbon sufficient to bring it to the state of No. 1 pig iron.

Peculiar
properties
of.

The peculiar property of steel, which renders it so valuable in the Arts, is, that it may be made extremely hard, or tempered to any degree between extreme hardness and the total absence of that property. These different states are produced by raising the temperature of the steel to a certain point, and then suddenly immersing it in cold water, or some other fluid. This property renders it extremely useful in the formation of various cutting tools, springs, &c. When very hard it is brittle, resists the file, yields sparks in collision with flint, and retains magnetism for a long time. Its hardness and temper are destroyed by heating to redness, and leaving it to cool gradually. It is malleable at a red heat, is less so at a white heat; and if exposed to a higher degree of temperature, it is fused, as already stated, and returns again to the state of pig iron; its point of fusibility being 130° of Wedgewood's pyrometer; but by being repeatedly heated and hammered it becomes again malleable iron, losing by this treatment its property of hardening by immersion in water.

Different
kinds of.

Steel is sometimes described as consisting of three different kinds, under the denomination of natural steel, steel of cementation, and cast steel. The natural steel, however, so called, owes its properties to the processes employed in the treatment of the ore, as the steel of cementation does to the treatment of the bar of iron; and cast steel is this latter fused and cast. Steel is also classified under the terms blistered steel, shear, or tilted, or German steel, and ingot or cast steel; the differences will be pointed out as we proceed.

Iron is converted into steel in what is called a cementing furnace, in which bars of iron are stratified with pounded charcoal, the form and construction of which will be understood by the following description given by Mr. Collier in vol. v. of the *Manchester Memoirs*.

Cementing
furnace.
Pl. xlv.
Fig. 1, 2.

(575.) *Cementing furnace for converting iron into steel.*—A furnace for this purpose is shown in plate xlv. fig. 1, 2; the first part, fig. 1, being a section through the middle A B, and fig. 2, a plan through the line D D. The same parts of the furnace are marked with the same letters in the two figures. E E are the pots or troughs into which the bars of iron are laid that are to be converted, contained in the square part within the circular building, which in its exterior form resembles a glass-house of 22 feet diameter and 32 feet high, the upper part being terminated in a dome, in the middle of which is a hole or chimney. F is the fire-place, P the bars of the grate, and R the ash-pit; G G, &c. are the flues. H H is an arch, the inside of the bottom of which corresponds with the line I I I, &c. and the top of it is made in the form of a dome having a hole or chimney in the centre K; L L L, &c. are six chimneys. M M the dome (resembling, as stated above, the usual figure

of a glass-house) covering the whole. At N there is an arched opening through which the materials are taken in or out of the furnace, and which is closely built up when the furnace is at work. At O O are holes in each trough, through which the ends of three or four of the bars are made to project quite out of the furnace. These are for the purpose of being drawn out occasionally to examine whether the iron is sufficiently converted.

Mechanical
Processes.

The troughs are made of fire-stone, or fire-tile, the bottoms of two courses, each course being about the thickness of the single course which forms the outsides of the troughs. The insides of the troughs are of one course, about double the thickness of the outside. The partitions of the flues are made of fire-brick, which are of different thicknesses as represented in the plan, and by dotted lines in the bottom of the troughs. These are for supporting the sides and bottoms of the troughs, and for directing the flame equally round them; the great object being to communicate to the whole an equal degree of heat in every part. The fuel is put in at each end of the fire-place, and the fire is made the whole length of the pots or troughs, and kept up as equally as possible during the process.

(576.) *Process of conversion.*—The furnace being prepared and bars of iron of a proper length, viz. a little less than the lengths of the troughs, and of a proper quality, Swedish iron being commonly preferred, a layer of charcoal dust is put upon the bottom of the trough, and upon that a layer of bar iron, and so on alternately till the trough is full. It is then covered over with clay to keep out the air, which, if admitted, would effectually prevent the cementation. When the fire is put into the grate, the heat passes round by means of the flues, made as shown in the figures by the sides of the troughs. The fire is continued till the cementation is complete, which generally happens in about eight or ten days. There is a hole, as has been stated, in the side, by which the workman draws out a bar occasionally to ascertain the degree to which the transmutation has proceeded. This is determined by the blisters upon the surface of the bars. If from the appearance the bars are not sufficiently changed, the hole is again carefully closed to exclude the air, and the process continued longer; but if, on the contrary, the change be complete, the fire is extinguished, and the steel is left to cool for about eight days more, when the process for forming the *blistered* steel is complete. It is thus denominated from the blisters above spoken of which are exhibited on its surface.

Process of
conversion.

For some common purposes the steel in this state is employed, but for others it is converted from blistered steel into *tilted steel*, *shear steel*, or *German steel*, and into *ingot* or *cast steel*.

(577.) *Shear or tilted steel* is formed from the bars of blistered steel. A number of these are laid together and temporarily fastened. In this state they are introduced into the fire and heated to a welding temperature, after which they are firmly united by means of the tilt hammer and drawn out; at a second heat these masses are beaten or rolled down into bars of about 1½ inch broad and ⅜ths thick. By this process, the loose parts and seams of the bars of blistered steel are closed together, and the steel is rendered susceptible of polish, of which it was before not capable. This additional hammering improves also the malleability, and renders it peculiarly applicable to the manufacturing of edge-tools, cutting instruments, shears, &c., and on this account it receives

Shear steel.

Manufactures.

its denomination of *shear* steel; having been formerly made at Newcastle, it is sometimes called *Newcastle* steel, but the better sort coming from Germany, it is frequently also called *German* steel.

Cast steel.

(578.) *Cast steel*.—This is blistered steel fused and run into ingots, a process which was first discovered in 1750, by Mr. Huntsman of Sheffield, and was for some time kept a great secret, but the Art is now pretty well known. The furnace employed for this purpose is an air furnace, and the vessel in which the fusion is made is a crucible formed of Stourbridge clay, mixed with a small quantity of powdered coke, which makes it less liable to crack in the heating or cooling, and at the same time gives it a considerable degree of stiffness in the fire when at the greatest heat. The covers of the crucibles are formed of a somewhat more fusible clay than the other part of the vessel, and are therefore sooner vitrified; by this means they become closely luted at the time the steel is at a temperature sufficiently high to be destroyed by the oxygen of the atmosphere. Coke of the hardest kind is commonly preferred for fuel in this process, as in all others where long continued and high temperatures are necessary. The crucibles are of sufficient size to contain about thirty pounds of steel, and in general each will bear charging three times. For making the best cast steel, the superior bars of blistered steel are used, broken into small pieces, but inferior cast steel is mostly made from scraps or the waste of manufactories. The vessels being charged and the fire applied a sufficient time, the steel becomes fused, and after remaining thus a proper time, it is cast into the form of ingots in cast iron moulds. These ingots are then drawn into bars under the tilt hammer, fit for the various purposes to which it is applied, as in all the finer sorts of cutlery, &c.

Various methods of working cast steel have been recommended, but frequently they have not been found practicable by those who have followed the directions given. Sir J. Franklin, in 1795, communicated a Paper on this subject to the Royal Society, *viz.* for welding steel and malleable iron together; but Mr. Collier, in his Paper in the *Manchester Memoirs* above referred to, says, from experiments he caused to be made, it appears that the author's plan can never succeed if the cast steel be of the best quality. But, perhaps, the best recorded account of the particular working properties of steel are those given in a series of Papers in the *Philosophical Magazine* by the late Mr. Mushet. He has shown that the hardness of iron increases with the carbon which it contains, till the carbon amounts to $\frac{1}{80}$ th of the iron. At that point the hardness is a maximum, the metal acquires the lustre and colour of silver, loses its granulated appearance, and assumes a crystallized form. If more than $\frac{1}{80}$ th of carbon be added, the hardness of the compound diminishes in proportion to its quantity.

The following Table by Mr. Mushet shows the proportions of carbon which combines with iron during the formation of the different carburets:

Soft cast steel.....	$\frac{1}{120}$
Common cast steel.....	$\frac{1}{100}$
The same steel but harder.....	$\frac{1}{90}$
The same, too hard for drawing.....	$\frac{1}{50}$
White cast iron.....	$\frac{1}{25}$
Mottled cast iron.....	$\frac{1}{20}$
Black cast iron.....	$\frac{1}{15}$

The following are the specific gravities of steel in different states:

Spec. grav.

Best blistered steel before hammering..	7.31
Ditto ditto after hammering..	7.73
Very hard steel.....	7.26
Melted steel wire.....	7.5
English cast steel hammered.....	7.82 to 7.91

Mechanical Processes.

(579.) *Hardening and tempering of steel*.—One of the most remarkable properties of steel, is that of its capability of being hardened by being first heated red-hot and then suddenly cooled by immersion in cold water, oil, or other fluid. The change is greater the hotter the steel is made, and the colder the fluid is into which it is plunged. The best method is to put the steel into a charcoal fire blown to a sufficient degree of heat by bellows, at least many workmen say that steel will not harden properly without a blast. When the fire is sufficiently hot, the substance to be hardened must be put in, and a gradual blast from the bellows continued till the metal has acquired a regular red heat; it is then to be rapidly quenched in cold water, at least in most common cases; but in hardening steel in thin plates, particularly when of cast steel, quenching in water would cause them to crack, and also make them too hard, and therefore in these cases recourse is had to some substance which is not so good a conductor of heat. Oil with tallow, bees-wax with resin dissolved in it, are therefore commonly employed instead of water in these cases.

Tempering steel is effected by again submitting it to the action of the fire; in doing this, as the heat increases the hardness decreases, and when it is thus reduced to that degree of hardness which the nature of the substance or instrument requires, it is again withdrawn from the fire and quenched in cold water or other fluid. The degree of hardness is judged of by the colour the metal takes in the several stages of the heating process, and artisans know the colour which gives the temper they require in their tool or instrument under operation. When elasticity is the object sought, as in springs for watches, for gun-locks, &c., the steel is quenched when it assumes a fine blue. When a fine edge is required, as in razors, the edge is brought to a fine straw colour, when the back is commonly blue. In other cases a bright red, or dark red, or dark brown indicates the proper temperature. In tempering steel for forming artificial magnets, the ends of the bars only are reduced to the blue colour. But the harder the whole bar is left, the better the magnetism will be retained, although it is the more difficult to impart the property to it, and not only is the process more difficult, but the steel in this state does not seem to possess so great a capacity for magnetism, but all that can be given to it will be retained with greater tenacity. The following Table was given by the late Mr. Stodart to Professor Brande, in which the degrees of heat of Fahrenheit's thermometer to which steel must be heated to give out the colours are stated as below; with any heat less than 430° no colour is produced.

1. Very pale straw yellow.....	430°
2. A shade of darker yellow.....	450
3. Darker straw yellow.....	470
4. Still darker straw yellow.....	490
5. A brown yellow.....	500
6. A yellow tinged slightly with purple.....	520
7. Light purple.....	530
8. Dark purple.....	550
9. Dark blue.....	570
10. Paler blue.....	590

Colours presented by steel at different temperatures.

Manufac-
tures.

11. Still paler blue610°
12. Still paler blue with a tinge of green....630

In the production of these colours, the access of oxygen is absolutely necessary in order that it may combine chemically with the metal.

Case-
hardening.

(580.) *Casehardening*.—Steel when hardened is brittle, and iron alone is not capable of receiving the hardness steel may be brought to possess. There is nevertheless a variety of articles in which it is desirable to possess all the hardness of steel, together with the toughness of iron. These requisites are united by the Art of case-hardening, which does not differ from the making of steel, except in the shorter duration of the process. Tools, utensils, or ornaments intended to be polished, are first manufactured in iron and nearly finished, after which they are put into an iron box, together with vegetable or animal coals in powder, and cemented for a certain time. This treatment converts the external part into a coating of steel, which is usually very thin, because the time allowed for the cementation is much shorter than when the whole is intended to be made into steel. Immersion of the heated pieces into water hardens the surface, which is afterwards polished by the usual methods. Moxon's *Mechanic Exercises*, p. 56, gives the following receipt: cow's horn or hoof is to be baked or thoroughly dried and pulverized. To this add an equal quantity of bay salt; mix them with stale chamber ley, or white wine vinegar; cover the iron with this mixture, and bed it in the same in loam, or enclose it in an iron box, lay it then on the hearth of the forge to dry and harden; then put it into the fire, and blow till the lump have a blood-red heat and no higher, lest the mixture be burned too much. Take the iron out and immerse it in water to harden.

Indian
steel.

(581.) *Indian steel or wootz*.—This is considered to be the finest of all steel for cutting instruments; it is made only in small quantities, and is expensive: the nature of its manufacture was unknown till very lately, and an imitation of it has been sought with some energy, without, however, arriving at a completely satisfactory result, although a near approach to it has been lately effected by Professor Faraday. The following account of the manufacture of wootz by the natives of India, was found in the manuscript Voyage of the late Dr. Voysey.

"The furnace is a temporary circular structure of clay, from four to five feet in height, and five feet in diameter; it is sunk two feet below the surface of the ground. The fuel is charcoal, and the fire is kept up by a blast from four bullock skins, placed at right angles to each other; the muzzles resting on the upper edge of the furnace, so as to force the blast downwards. The granitic clay of the furnace is highly infusible; it is found in the neighbourhood, and is formed of the decomposition of granite rock with small pieces of quartz and felspar, and is so valued for its refractory qualities, that it is exported for the manufacture of crucibles, &c. After some days, however, if a considerable heat has been maintained, the furnace becomes semi-vitrified, and requires renewal. The cost of a furnace is from two to three rupees.

"The bellows are plied incessantly day and night; during the operation, the men are relieved every four hours, each being engaged to work twelve out of the twenty-four. They are partly protected by a screen of mud placed between them and the furnace, but the heat and exertion render their task sufficiently laborious.

"The iron is converted into steel in pine-shaped crucibles made of the same clay as the furnace, and of various sizes, according to the purpose for which the steel

is to be applied, whether for the fabrication of swords, or knives, or other articles.

Mechanical
Processes.

"In making the crucibles, the granitic clay above described is ground to a fine powder with the fragments of old furnaces and crucibles, and the whole kneaded together with the chaff of rice and oil. The vessels are defended by a luting of the same; they are covered with a similar top, but a perforation is made in the latter. No charcoal is put into the crucible, but small pieces of kanch, or the glass formed in the process, are put at the bottom of them along with the ore, and serve of course as a flux. The crucibles are arranged and steadied in the furnace occasionally by the superintendent with a long and stout rod of iron.

"The materials used in the preparation of the steel are two different kinds of iron; one from Mirtpalli, the other from Kondapur, in the proportion of three parts of the former to two of the latter. The Mirtpalli iron is derived originally from the iron sand already noticed, and is sent in the state of large amorphous masses of a reddish-grey colour, and of an extremely porous texture. The internal fracture is often iridescent. The Kondapur iron is procured from an ore found amongst the iron clay, at a place about twenty miles distant. It is said to be of a dirty brown colour, and very frangible. The iron, however, is moderately compact and of a brilliant white fracture. Occasionally it contains some ingredient which spoils the steel, rendering it excessively brittle: the natives assert that the adulteration is copper, but it is more probably arsenic. The mixture being put into the crucible, the fire is excited and kept up for twenty-four hours. It is then allowed to subside, and the crucible is taken out and placed on the ground to cool. When quite cold it is opened and a cake of steel of great hardness is found weighing on an average about a pound and a half. The cake is covered with clay and annealed in the furnace for twelve or sixteen hours; it is then taken out and cooled and again annealed; and this may be repeated a third or fourth time until the metal is rendered sufficiently soft to be worked.

"The following experiments may convey some notion of the degree of heat to which these furnaces can be raised, and which may be reckoned at 130° of Wedgwood; twenty-five rupees weight of steel which had not been submitted to the last operation, with $\frac{1}{16}$ th of a silver rupee, was fused in three hours into a button of hard steel. A piece of shelly stratum from Jhirpa fused into a sort of porcelain. A piece of hornblende schist was fused into a glass, with many globules of iron and manganese floating on the surface. The granite from the bed of the Godaveri yielded a green glass. Belkonda granite was partly run into a green glass with pieces of quartz little altered floating on the mass. Sitabaldi basalt was melted into a yellowish-green, and Jhirpa wacken into a very perfect opaque black glass."

(582.) *Damascus steel*.—This is a celebrated description of steel highly preferred for swordblades. It is generally supposed to be made of slips of thin rods or wires of iron and steel, bound together with iron wire and then melted together by heat. The most skilful workmen, however, of other Countries have in vain attempted to imitate the process, so that there is reason to think that the secret of its manufacture is unknown in Europe. The colour of the Damascus blades is a dull bluish-grey, and it scarcely exceeds in hardness common steel from the forge. Its appearance is very peculiar, showing a watery or wavy surface, which on swordblades runs from the hilt to the point, exhibiting narrow lines of about the thickness of a

Damascus
steel.

Manufactures.

harpsichord wire and which never cross each other. These wavy lines arise from a slight difference in the degrees of polish occasioned by the unequal action of acid upon the steel. This appearance has been imitated by false damasking or etching, but the genuine Damascus blade is distinguished from the false one by grinding, the waving line being obliterated by this process in the false blade, but remaining the same throughout in the real one. In the real blade, indeed, the grinding at first seems to have destroyed the watering, but it immediately reappears by rubbing it with lemon juice.

Alloys of steel.

(583.) *Alloys of steel.*—Very curious and instructive experiments on the alloys of steel with several metals, with a view to improve cutting instruments and reflecting mirrors, were made a few years back in the Laboratory of the Royal Institution, of which an account is inserted in the 18th Number of the *Journal of Science*.

Alloys of steel with platinum, rhodium, gold, and nickel may be obtained when the heat is sufficiently high. This is so remarkable with platinum, that it will fuse when in contact with steel at a heat at which the steel itself is not affected.

There are some very curious circumstances attending the alloy of silver. If steel and silver be kept in fusion together for a length of time, an alloy is obtained, which appears to be very perfect while the metals are in the fluid state, but on solidifying and cooling, globules of pure silver are expressed from the mass, and appear on the surface of the button. If an alloy of this kind be forged into a bar, and then dissected by the action of dilute sulphuric acid, the silver appears not in combination with the steel, but in threads throughout the mass; so that the whole has the appearance of a bundle of fibres of silver and steel, as if they had been united by welding. The appearance of these silver fibres is very beautiful; they are sometimes one-eighth of an inch in length, and suggest the idea of giving mechanical toughness to steel, where a very perfect edge may not be required. The most interesting result is the following. When one of silver and five hundred steel were properly fused together, a very perfect button was produced, no silver appeared on its surface; when forged and dissected by an acid, no fibres were seen, although examined by a high magnifying power. The specimen forged remarkably well although very hard; it had, in every respect, the most favourable appearance. By a delicate test, every part of the bar gave

silver. This alloy is decidedly superior to the very best steel, and this excellence is unquestionably owing to combination with a minute portion of silver. It has been repeatedly made, and always with success. Various cutting tools have been made from it of the best quality. Mr. Stodart, a very eminent cutler, assisted at these experiments, which must give the public confidence in their practical results.

Equal parts, by weight, of platinum and steel form a beautiful alloy, which takes a fine polish, and does not tarnish; the colour is the finest imaginable for a mirror. The specific gravity of this beautiful compound is 9.862. The proportions of platinum that appear to improve steel for edge instruments are from 1 to 3 per cent. While an alloy of 10 platinum with 80 steel, after lying many months exposed, had not a speck on its surface, an alloy of 10 nickel with 80 platinum was in the same circumstances covered with rust.

The alloys of steel with rhodium would prove highly valuable were it not for the scarcity of the latter metal.

Messrs. Stodart and Faraday, in a new Memoir on these alloys, published in the *Philosophical Transactions* for 1822, part ii., observe that "when pure iron is substituted for steel, the alloys so formed are much less subject to oxidation: three per cent. of iridium and osmium fused with pure iron gave a button, which, when forged and polished, was exposed with many other pieces of iron, steel, and alloys, to a moist atmosphere: it was the last of all in showing any rust. The colour of this compound was distinctly blue; it had the property of becoming harder when heated to redness and quenched in a cold fluid. On observing this steel-like character, the presence of carbon was suspected; none, however, was found, although it was carefully looked for. It is not improbable that there may be other bodies besides charcoal capable of giving to iron the properties of steel; and the authors, though they cannot agree with M. Boussingault when he would replace carbon in steel by silica or its base, they think his experiments very interesting on this point, which is worthy of further examination notwithstanding the above results. The Editor of the *Journal of Science*, in commenting upon the above alloys, considers that "a bar of the best ordinary steel, selected with precaution and most carefully forged, wrought, and tempered under the immediate inspection of the master, would afford cutting instruments as perfect and excellent as those composed of wootz or of the alloys."—*Journal*, xiv. p. 378.

Copper.

Copper. Process of smelting.

(585.) *Copper*, as we have seen in our article *Mining*, is obtained in considerable quantities in Cornwall, and in other parts of England and Wales. In that article we have explained the processes employed in extracting the ore, and the stamping of it in order to reduce it to a state fit for smelting. It remains for us now to describe the methods had recourse to for extracting the metal from the ore and the reduction of it to malleable copper. The only ores of copper which are wrought in the large way, and from which the copper of commerce is for the most part supplied, are the sulphureous and arsenical ores of this metal. The processes the ores undergo before the metal is rendered sufficiently pure, are numerous on account of the tenacity with which both the sulphur and arsenic combine with the copper, but they are extremely simple, and may be readily explained, consisting of little more than repeated roastings and fusions till the metal has attained the necessary ductility.

First, as we have before described, the ores are broken into small pieces. They are then, in Cornwall, roasted in a furnace of the reverberatory kind, having a very long chimney to increase the heat and to carry off the sulphur and arsenic. During the roasting, which continues about twelve hours, the ore is frequently stirred in order to expose the whole of it to the flame. It is then put into a smaller furnace, of the same form, and brought to a state of fusion, being occasionally mixed with a little lime to increase the fusibility. During this process, scoriæ containing various impurities rise and float on the surface, which are raked out and run into oblong moulds where they are left to cool, when they become hard masses and are used in building. The fused metal, which sinks by its gravity, is run out through a hole in the lower part of the furnace, which during the process of fusion is stopped with a mixture of earth and clay, as described in the article *Iron Blast Furnace*. The fused copper is conveyed into vessels suspended in a well, through which a stream of water runs, by which sudden cooling the metal is reduced to a granular state, although it is still very impure, being still mixed with sulphur and arsenic. To free it more completely from these, it is repeatedly submitted to a reverberatory furnace, and each time put into the well. In each of these fusions a

slag is continually formed on the surface more thin each time, but as this slag contains in it some copper, it is preserved and mixed with the fresh ore previously to its being put into the furnace.

After these processes have been repeated a sufficient number of times, the copper is kept at a low red-heat for two days, and is then repeatedly fused and cast into moulds about fourteen inches in length. Lastly, it is put into the refining furnace with a little charcoal, in which it is again fused; it will then bear the hammer and is fit for sale. In Anglesea, the ores are wrought nearly in the same way, but there after the ore is reduced to fragments, it is put into a kiln, the flues of which terminate in a close chamber. Heat is then applied to the ore, and the sulphur which sublimes is carried through the flue and condenses in the chamber; fresh quantities of the ore are from time to time added, and the roasting in this way is carried on for several months. The sulphur is afterwards collected, fused, and run into moulds, forming what is called brimstone. See *Sulphur Works*.

The smelting the ore is conducted after the manner above described, and it is stated that about twelve hundred weight of the roasted ore yields about one-quarter of malleable metal, and each charge of the furnace of twelve hundred weight is finished in about five hours.

In Hungary, the copper ore is treated in the same way, but the purification of the metal is accomplished by means of lead; for that purpose the metal is fused in a furnace and about one-twelfth or one-fifteenth of lead is added; this forms a scoria with the impurities of the copper, which is removed as it is formed and the copper is left in its pure state, after which it is kept fused for some time. To ascertain when the whole of the impurities of the copper have been removed, the workman takes out a little of the melted metal on the end of a smooth iron rod. If the metal be pure, this falls off when it is dipped into cold water.

The purity of the metal is also known by the redness of the scoria, that of the impure copper being always dark coloured.

The thin sheets of copper used in the Arts, are prepared when the metal is in a state of fusion in the furnace. For this purpose, when the whole of the impurities have been removed, the metal is allowed to cool to near its point of congelation. A wet broom is then

Refining.

Method of forming thin sheet copper.

Manufac-
tures.

drawn along its surface, by which means a thin layer of it is made to pass into the solid state. This is removed, and immediately plunged into water, by which it acquires a fine red colour; and the process is repeated till the whole is formed into thin sheets.

Copper
obtained by
precipita-
tion.

Copper, in a state of considerable purity, is sometimes procured from the springs which contain the sulphate of this metal. With this view, pieces of iron are put into

the water, by which the copper is precipitated, owing to the superior affinity of the iron for the acid, aided, perhaps, by a galvanic action. When the whole of the iron is dissolved, the matter deposited is raked out, and is fused in a furnace, either alone or mixed with some of the poorer copper ore.

Mechanical
Processes.

The deposit obtained in this way, when fused alone, commonly yields about fifty per cent. of copper.

Tin.

Reduction
of the ores
of tin.

(587.) The ores of tin are reduced in several different ways: in Cornwall, generally after being stamped, as described in our article on Mining. It is roasted in a reverberatory furnace to drive off the sulphur, part of which is, however, acidified and unites with the copper and iron also contained in the ore; after this the ore is again washed, by which it is nearly freed from all its impurities; it is

then mixed with about one-fifth of its bulk of culm, and subjected again to the furnace for about six hours, during which the oxide of tin is reduced, and the metal collects at the bottom covered with a black scoria. The metal is then drawn off into a shallow pit, in which it is freed from scoria on its surface; it is then taken out with ladles and run into moulds. The metal thus obtained is afterwards exposed to a gentle heat in a small reverberatory furnace, by which the purest part of the metal

Manufactures

first melts, and is drawn off. This forms grain tin; what is left behind is common tin, still containing a small portion of iron, copper, and arsenic.

The water employed in the second washing contains a considerable quantity of sulphate of copper, on which account it is preserved to be afterwards decomposed by iron, and the scoria separated from the tin when drawn from the furnace, retains a good deal of the metal; this, therefore, is also reserved to be again stamped and re-melted with fresh ore.

Reduction of stream tin.

The above process is followed only for the raised ore; what is called the stream tin undergoes a different process. As the ore is here in a state approaching to powder by its first washing, and as a great many of the impurities with which it is combined in the other state are already removed, the first operation is to bruise it and pass it through wire sieves; it is then thrown with alternate layers of charcoal into a blast furnace, in which it is reduced and runs out, through a channel in the bottom, into pits, the scoria being removed as it collects and thrown again into the furnace. After this the metal is put into a large iron pot, in which it is kept in a state of fusion; and while in this state, pieces of charcoal are plunged into it, which cause a fresh quantity of scoria to be formed, and separated from the metal. It is then tried or tested by removing a quantity in a ladle and pouring it into the pot, and if it appears bright like silver and of uniform consistence, it is considered pure, and is poured into moulds, being in a state fit for the market.

Lead.

Lead ore, where found.

(588.) Another useful metal found in England, is lead; it is also very common in most Countries. In England it is found in Cornwall, Devonshire, Somersetshire, Durham, Lancashire, Cumberland, Westmoreland, and partially in other Counties; in Wales, in Flintshire, Denbighshire, Merionethshire, and Montgomeryshire; and in Scotland, in Dumfries-shire, Lanarkshire, Ayrshire, and Argyleshire. The only ore of lead from which the metal

is extracted is galena, the smelting of which is very simple. This is performed either by a blast furnace, called an ore hearth, or in a reverberatory furnace. In the former method, the ore and fuel are mixed together and exposed to the action of the blast, which quickly fuses the metal and causes it to fall into the lower part of the hearth, where it is protected from the oxygen of the blast by the scoria which floats upon its surface. When the fluid is drawn off, a sufficient quantity of it is left in the furnace to float the scoria, but when the whole is drawn off, the blast is stopped, and some lime is thrown into the furnace to concrete the scoria while the heat is being discharged. In the reverberatory furnace, which is preferred in places where there is a plentiful supply of coals, the fire is made at one end, and the flame passes over the hearth and up a flue, as already described for such furnaces in general.

Mechanical Processes.

In the latter case, the ore being already stamped and freed from as much earthy matter as possible, is put into a riddle or sieve and placed in a large vessel full of water; when by a certain motion obtained, by practice, the lighter and earthy particles are separated and thrown over the edges of the riddle, while the metallic part, being of course heavier, is retained at the bottom. With this, however, there are many impurities which can be separated only in the furnace.

Here commences the smelting process. The cleansed ore is spread upon the concave hearth, so that the flame may act upon it and release the sulphur; when this has escaped, the lead combines with the oxygen, and the oxide of lead thus formed combines with and reduces the earthy matter to a liquid which floats upon the surface of the metal, and for the rest of the operation protects it from the action of the oxygen. The temperature of the furnace is now considerably raised to separate as quickly as possible the lead from the liquid scoria; after which a great portion of the scoria is tapped off, leaving only so much behind as is necessary to protect the metal from the action of the oxygen. The fire is now slackened and a quantity of slack, or refuse pit-coal, is thrown into the furnace, which serves to diminish the heat, and to concrete the melted scoria; though this last part of the process is not well done unless powdered lime be also added. The scoria being now hardened, is broken to pieces by a rake, and thrust to the opposite side of the furnace, where it is taken out through apertures formed for the purpose. The lead is now tapped, in a manner similar to that described in the manufacture of iron, and is allowed to run into a large iron pan, where it is laded into moulds to be cast into pigs. When the ores abound with sulphate of iron, it becomes necessary to add the fluete of lime as a flux.

The scoria is still found to contain some lead, independently of that in the state of oxide, and chemically combined with it; it is therefore exposed to the heat of another furnace, being a species of blast furnace, called a slag hearth, which fuses the scoria, and causes the metal to penetrate through it, and fall into a cavity, where it is protected from the agency of the blast, and whence it is taken and cast into pigs.

Silver.

Silver ores

(590.) Silver ores, properly so called, are very rare in England, but some instances of them have occurred. The silver, however, produced in this Country, is extracted principally from lead ores, which commonly contain more or less of silver, but it is only when the latter amounts to a certain per centage that it will answer the purpose of a proprietor to attempt to extract it.

We learn from some of our early Historians, that silver was formerly extracted from mines in various parts of England and Wales. In the reign of Edward I. sixteen hundred pounds weight of silver was obtained in the course of three years, from a mine in Devonshire, which had been discovered towards the beginning of this reign; and is called a silver mine by the old writers, but it appears to have been only a mine of lead that contained silver. The lead mines in Cardiganshire have also at different periods afforded great quantities of this metal. Sir Hugh Middleton is said to have cleared from them two thousand pounds per month, and to have been enabled thereby to undertake the great work of bringing the New River from Ware to London. The same mines yielded, in the time of Charles I., eighty ounces of silver in every ton of lead, and part of the King's army was paid with this silver, which was minted at Shrewsbury. Sir J. Pettre's *Essay on Metal Works*.

A mint for the coinage of Welsh silver had been previously established at Aberystwith: the indenture was granted to Thomas Bushel, for the coinage of half-crowns, shillings, sixpences, twopences, and pennies, and the moneys were to be stamped with the ostrich feather on both sides. In 1604, nearly three thousand ounces of this Welsh bullion were minted at one time at the Tower. Webster, in his *History of Metals*, published in 1671, makes mention, from his own knowledge, of two places in Craven, in the West Riding of Yorkshire, where formerly good argentiferous lead ore had been procured. One of the places was Bronghite Moor, in the parish of Slaidburn; the ore held about the value of sixty-seven pounds of silver in the ton: the other was at Skelhornfield, in the Parish of Gisburn; it had formerly belonged to a person of the name of Pudsey, who is supposed to have coined it, as there were many shillings in that County which the common people

called Pudsey shillings. There are several smelting houses at Holywell, in Flintshire, where silver is extracted from lead; and according to Mr. Pennant, at one of the largest of these houses, in the year 1754, more than twelve thousand ounces of silver were produced, but in the subsequent years, the quantity appears to have been considerably diminished. The silver extracted from lead is sold principally to the manufacturers at Sheffield and Birmingham.

In later times, also, considerable quantities of silver have been obtained from British mines, of which the lead mines of Beralston, Devonshire, furnishes the richest supply. This mine is 110 fathoms deep, and is worked under the Tamar, and the vein which was being worked when the author visited this mine, was stated to yield about seventy ounces of silver to a ton of lead; but it has since, we believe, much declined, and the process of extraction has been discontinued. According to Mr. Mawe, it appears that at the copper mine called Huel Jewel, about four miles South-East of Callington, native silver and lead ore and certain other silver ores were found which promised well at first, but soon failed. In a lead mine at Truro, the produce of silver was one hundred ounces of silver to a ton of lead. Little silver is at this time, however, obtained from the lead works of England, and we shall not therefore detain the reader with more than a simple description of the process of extracting it. We may just add, that according to the present comparative price of lead and silver, it will not answer the purpose of a proprietor to undertake the process unless the amount of silver exceeds twenty ounces to the ton of lead.

(591.) *Process of extracting silver from lead.*—This is effected by oxidating the latter metal in a reverberatory furnace, of a particular construction for the admission of air on the surface of the lead in a state of fusion. With this object, a shallow vessel or cupel is employed, filled with prepared fern ashes, well rammed down, out of which a concavity is cut out for the reception of the lead, with an opening on one side for the mouth of the bellows, through which the air is forcibly driven during the process. The French smelters cover the surface of the ashes with hay, and arrange the pieces of lead symmetrically upon it. When the fire is lighted and the lead is in a state of fusion from the reverberation of the flame,

Extracting silver from lead.

Manufac-
tures.

the blast from the bellows is made to play forcibly on the furnace, and in a short time a crust of yellow oxide of lead, or litharge, is formed, and driven to the side of the cupel opposite to the mouth of the bellows, where a shallow side or aperture is made for it to pass over; another crust of litharge is formed and driven off, and this is repeated in succession till nearly all the lead has been converted into litharge and removed. The operation continues about forty hours, when the complete separation of the lead is indicated by a brilliant lustre on the convex surface of the melted mass in the cupel, which is occasioned by the removal of the last crust of litharge that covers the silver. The French introduce water through a tube into the cupel, to cool the silver rapidly, and to prevent its spirting out, which it does when the refrigeration is gradual, owing, probably, to its tendency to crystallize. In England, the silver is left to cool in the cupel, and some inconvenience is caused by the spirting, which might be avoided by the former mode.

The silver thus extracted is not sufficiently pure; it is again refined in a reverberatory furnace; being placed in a cupel lined with bone ashes, and exposed to greater heat, the lead which has escaped oxidation by the first process is converted into litharge, and absorbed by the ashes of the cupel. The last portions of litharge in the first process are again refined for silver, of which it contains a part which was driven off with it. The litharge is converted into lead again by heating it with charcoal; part is sometimes sold for pigment, or converted into red lead. The loss of lead by this process differs considerably, according to its quality.

Zinc.

Reduction
of zinc ores.

(592.) The ores of zinc used in Metallurgy are calamine and blend, and from these the metal is procured by a very simple process, although differing in some respect from those already described. It may be observed, however, that the methods adopted in different Countries are various, but the following is perhaps the most simple. The ore after being dressed, and the pieces of lead frequently mixed with it removed, is roasted in order to expel the sulphur, acids, and other foreign matter. The product is then washed, by which the lighter matter is separated, and the heavy part which remains is mixed with one-eighth of its weight of charcoal. The mixture is next reduced to powder in a mill, in which state it is put into pots to be smelted. The pots in which the smelting is performed, resemble oil jars in shape. Through the bottom of each there passes a tube, the upper end of which terminates by an open mouth near the top of the pot, the lower end goes through the floor of the furnace into water. The pots are filled to the upper end of the tube with the mixture of ore and charcoal, and an intense heat is applied to them by means of a furnace. As the ore is reduced, the zinc is volatilized, and escapes through the tube into the water, where it is condensed in the form of globules. These are afterwards melted and cast into moulds.

Zinc, as thus procured, is not pure; it almost always contains iron, manganese, arsenic, and copper. To free it from these, it is again melted and then well stirred with sulphur and fat, the former of which combines with the foreign metals, and leaves the zinc nearly pure, while the latter prevents this metal from being oxidated.

The zinc used in England is chiefly imported, very

little having ever been produced in this Country. It appears that in 1731, the price of zinc amounted to £260 per ton, and soon after, viz. 1738, Mr. Champion of Bristol obtained a patent for manufacturing it from English ores. Up to 1750, he had made about two hundred tons; but the price having fallen very considerably, notwithstanding the English zinc had the preference in the market, he petitioned Parliament for an enlargement of his patent, stating, that, in consequence of the great reduction in the price, he should otherwise be a great loser by his discovery.

Mechanical
Processes.

Platina.

(593.) This is a metal for the discovery of which we are indebted to modern times. Although the ore is not the product of British mines, the best method of working it was the discovery of an eminent British Chemist, the late Dr. Wollaston; and as the reduction of the crude platina to a malleable metal constitutes the principal art connected with it, we do not hesitate to introduce it amongst the manufactures which are generally confined to those of England only. Dr. Wollaston, for many years, kept his mode of operation secret, and he is said to have acquired a considerable fortune in the manufacture of the metal; but a short time before his death, he communicated his process to the Royal Society, and we cannot do better than give the reader the short but important Paper in the author's own words, who commences by observing:

"As from long experience, I probably am better acquainted with the treatment of platina, so as to render it perfectly malleable, than any other Member of this Society, I will endeavour to describe, as briefly as is consistent with perspicuity, the processes which I put in practice for this purpose, during a series of years, without seeing any occasion to wish for further improvement.

Dr. Wollas-
ton's pro-
cess de-
scribed.

"The usual means of giving chemical purity to this metal, by solution in aqua regia and precipitation with sal ammoniac, are known to every Chemist, but I doubt whether sufficient care is usually taken to avoid dissolving the iridium contained in the ore by due dilution of the solvent. In an account which I gave in the *Philosophical Transactions* for 1804, of a new metal, rhodium, contained in crude platina, I have mentioned this precaution, but omitted to state to what degree the acids should be diluted; I now therefore recommend, that to every measure of the strongest muriatic acid employed, there be added an equal measure of water; and moreover, that the nitric acid used be what is called 'single aquafortis;' as well for the sake of obtaining a purer result, as of economy in the purchase of nitric acid.

"With regard to the proportions in which the acids are to be used, I may say, in round numbers, that muriatic acid, equivalent to 150 marble, together with nitric acid equivalent to 40 marble, will take 100 of crude platina; but in order to avoid waste of acid, and also to render the solution purer, there should be in the menstruum a redundancy of 20 per cent. at least of the ore.

"The acids should be allowed to digest three or four days, with a heat which ought gradually to be raised. The solution, being then poured off, should be suffered to stand until a quantity of fine pulverulent ore of iridium, suspended in the liquid, has completely subsided, and should then be mixed with 41 parts of sal am-

Manufac-
tures.

moniac, dissolved in about 5 times their weight of water. The first precipitate, which will thus be obtained, will weigh about 165 parts, and will yield about 66 parts of pure platina.

"As the mother-liquor will still contain about 11 parts of platina, these, with some of the other metals yet held in solution, are to be recovered by precipitation from the liquor with clean bars of iron, and the precipitate is to be redissolved in a proportionate quantity of aqua regia, similar in its composition to that above directed to be used: but in this case, before adding sal ammoniac, about one part by measure of strong muriatic acid should be mixed with 32 parts by measure of the nitromuriatic solution, to prevent any precipitation of palladium or lead along with the ammonio-muriate of platina.

"The yellow precipitate must be well washed, in order to free it from the various impurities which are known to be contained in the complicated ore in question; and must ultimately be well pressed, in order to remove the last remnant of the washings. It is next to be heated, with the utmost caution, in a black lead pot, with so low a heat as just to expel the whole of the sal ammoniac, and to occasion the particles of platina to cohere as little as possible; for on this depends the ultimate ductility of the product.

"The grey product of platina, when turned out of the crucible, if prepared with due caution, will be found lightly coherent, and must then be rubbed between the hands of the operator, in order to procure by the gentlest means, as much as can possibly be so obtained, of metallic powder, so fine as to pass through a fine lawn sieve. The coarser parts are then to be ground in a wooden bowl with a wooden pestle, but on no account with any harder material, capable of burnishing the particles of platina, since every degree of burnishing will prevent the particles from cohering in the further stages of the process. Since the whole will require to be well washed in clean water, the operator, in the latest stages of grinding, will find his work much facilitated by the addition of water, in order to remove the finer portions as soon as they are sufficiently reduced to be suspended in it.

"Those who would view this subject scientifically, should here consider, that as platina cannot be fused by the utmost heat of our furnaces, and consequently cannot be freed, like other metals, from its impurities, during igneous fusion, by fluxes, nor be rendered homogeneous by liquefaction, the mechanical diffusion through water should here be made to answer, as far as may be, the purposes of melting; in allowing earthy matters to come to the surface by their superior lightness, and in making the solvent powers of water effect, as far as possible, the purifying powers of borax and other fluxes in removing soluble oxides.

"By repeated washing, shaking, and decanting, the finer parts of the grey powder of platina may be obtained as pure as other metals are rendered by the various processes of ordinary metallurgy; and if now poured over, and allowed to subside in a clean basin, a uniform mud or pulp will be obtained ready for the further process of casting.

"The mould which I have used for casting, is a brass barrel, $6\frac{3}{4}$ inches long, turned rather taper within, with a view to facilitate the extraction of the ingot to be formed, being 1.12 inch in diameter at top, and 1.23 inch at a quarter of an inch from the bottom, and plugged at its larger extremity with a stopper of steel,

that enters the barrel to the depth of a quarter of an inch. The inside of the mould being now well greased with a little lard, and the stopper being fitted tight into the barrel by surrounding it with blotting paper, (for the paper facilitates the extraction of the stopper, and allows the escape of water during compression,) the barrel is to be set upright in a jug of water, and is itself to be filled with that fluid. It is next to be filled quite full with the mud of platina; which subsiding to the bottom of the water, is sure to fill the barrel without cavities, and with uniformity,—a uniformity to be rendered perfect by subsequent pressure. In order, however, to guard effectually against cavities, the barrel may be weighed after filling it, and the actual weight of its contents being thus ascertained, may be compared with that weight of platina and water which is known by estimate that the barrel ought to contain. A circular piece of soft paper first, and then of woollen cloth, being laid upon the surface, allow the water to pass, during partial compression by the force of the hand with a wooden plug. A circular plate of copper is then placed upon the top, and thus sufficient consistency is given to the contents to allow of the barrel being laid horizontally in a forcible Press.

"The Press which I have generally used for this purpose is represented in plate xlv. fig. 3: it consists of a flat iron bar A B, set edgewise and screwed down by a hook E near its middle, where it would otherwise be liable to bend, to a strong wooden bench C D. The bar is connected, by a pivot at its extremity A, with the lever A F G; an iron rod F H, which turns at its two extremities upon the pivots F and H, proceeds from the lever at F, and, as the lever descends, propels forward the carriage I, which slides along the bar. A stopper or block being placed in the vacant space I K, the carriage communicates motion to the cradle *k l m*, which is also made to slide along the bar, and carries the barrel N, which lies upon the cradle, straight against the piston O O, which rests by its end against P, a projection in the further extremity of the bar.

"The weight which in this Machine, when the angle of the lever's elevation is small, will keep the power, applied vertically at the extremity of the lever, in equilibrium = that power $\times \frac{AG \times FH}{AF(AF + FH)} \times \cotan.$ of the

angle of the lever's elevation; which expression, in the case of the Press actually used, becomes, power $\times 5$, $\cotan.$ of the angle of the lever's elevation. This expression, at an elevation of 5° , becomes nearly $60 \times$ power, and at an elevation of 1° becomes nearly $300 \times$ power; and when the lever becomes horizontal the multiplier of the power becomes *quasi* infinite. This explanation will be sufficient to show the mechanical advantage with which, by means of this Press, the weight of the operator, acting on the end of the lever, will be made to bear against the area of the section of the barrel, a circle a little more than an inch in diameter.

"After compression, which is to be carried to the utmost limit possible, the stopper at the extremity being taken out, the cake of platina will easily be removed, owing to the conical form of the barrel; and being now so hard and firm that it may be handled without danger of breaking, it is to be placed upon a charcoal fire, and there heated to redness, in order to drive off moisture, burn off grease, and give to it a firmer degree of cohesion.

"The cake is next to be heated in a wind furnace,

Mechanical
Processes.

Press employed in
the process
Pl. xlv.
Fig. 3.

Manufac-
tures.

and for this purpose is to be raised upon an earthen stand about $2\frac{1}{2}$ inches above the grate of the furnace, the stand being strown over with a layer of clean quartzose sand, on which the cake is to be placed, standing upright on one of its ends. It is then to be covered with an inverted cylindrical pot, of the most refractory crucible ware, resting at its open end upon the layer of sand, and care is to be taken that the sides of the pot do not touch the cake.

"To prevent the blistering of the platina by heat, which is the usual defect of this metal in its manufactured state, it is essential to expose the cake to the most intense heat that a wind furnace can be made to receive, more intense than the platina can well be required to bear under any subsequent treatment, so that all impurities may be totally driven off, which any lower temperature might otherwise render volatile. The furnace is to be fed with Staffordshire coke, and the action of the fire is to be continued for about twenty minutes from the time of lighting it, a breathing heat being maintained during the last four or five minutes.

"The cake is now to be removed from the furnace, and, being placed upright upon an anvil, is to be struck, while hot, on the top, with a heavy hammer, so as at one beating effectually to close the metal. If in this process of forging the cylinder should become bent, it should on no account be hammered on the side, by which treatment it would be cracked irremediably; but must be straightened by blows upon the extremities dexterously directed, so as to reduce to a straight line the parts which project.

"The work of the operator is now so far complete, that the ingot of platina may be reduced, by the processes of heating and forging, like that of any other metal, to any form that may be required. After forging, the ingot is to be cleaned from the ferruginous scales, which its surface is apt to contract in the fire, by smearing over its surface with a moistened mixture of equal parts, by measure, of crystallized borax and common salt of tartar, which, when in fusion, is a ready solvent of such impurities, and then exposing it, upon a platina tray, under an inverted pot, to the heat of a wind furnace. The ingot, on being taken out of the furnace, is immediately to be plunged into dilute sulphuric acid, which in the course of a few hours will entirely dissolve the flux adhering to the surface. The ingot may then be flattened into the leaf, drawn into wire, or submitted to any processes of which the most ductile metals are capable.

"The perfection of the methods above described for giving to platina complete malleability, will best be estimated by comparing the metal thus obtained, in respect of its specific gravity, with platina which has undergone complete fusion; and by comparing it, in respect of its tenacity, with other metals possessing that quality in the greatest perfection.

Specific
gravity of
platina.

"The specific gravity of platina, drawn into fine wire from a button, which had been completely fused by the late Dr. E. D. Clarke with an oxyhydrogen blowpipe, I found to be 21.16. The aggregate specific gravity of the cake of metallic mud, when first introduced into the barrel, exclusively of moisture, is about 4.3; when taken from the Press, is about 10; that to which the cake fully contracted, on being taken out of the wind furnace before forging, is from 17 to 17.7. The mean specific gravity of the platina after forging is about 21.25, although that of some rods after being drawn is 21.4; but that

of fine platina wire, determined by comparing the weight of a given length of it with the weight of an equal length of gold wire drawn through the same hole, I find to be 21.5; which is the maximum specific gravity that we can well expect to be given to platina.

Mechanical
Processes.

"The mean tenacity, determined by the weights required to break them, of two fine platina wires, the one of $\frac{1}{3000}$ the other of $\frac{1}{3850}$ of an inch in diameter, reduced to the standard of a wire $\frac{1}{10}$ th of an inch in diameter, I found to be 409 pounds; and the mean tenacity of 11 wires, beginning with $\frac{1}{4500}$ and ending with $\frac{1}{25000}$ of an inch, reduced to the former standard, I found to be 589 pounds; the maximum of these 11 cases being 645 pounds, and the minimum 480 pounds. The coarsest and the finest wire which I tried present exceptions; since a wire of $\frac{1}{1500}$ of an inch gave 290 pounds, and a wire of $\frac{1}{30000}$ of an inch, 190 pounds. If we take 590 pounds, as determined by 11 consecutive trials, to be the measure of the tenacity of the platina prepared by the processes above described, and consider that the tenacity of gold wire, reduced to the same standard, is about 500, and that of iron wire 600 we shall have full reason to be satisfied with the processes detailed in the present Paper, by which platina has been rendered malleable."—*Phil. Trans.* for 1829.

Tenacity of
the wire.

Alloys of Metals. Brass.

(594.) This compound metal was known to the Ancients, as we find by many parts of the Old Testament, as well as from various ancient Historians, but it does not appear that they were properly acquainted with its nature or composition. They considered it as a particular kind of copper, found native in the mines in which zinc and copper seem to have been found in the proper proportions for its production: it was denominated by the Greeks *Orichalcum*, i. e. *Æs montanum*, a particular sort. *Æs Corinthiacum* is generally supposed to have been a mixture of gold, silver, and copper, metals with which Corinth abounded, melted down together at the burning of this city by the Romans in A. C. 496. At what time the actual constitution of brass became known, is not stated with any certainty, but it appears unquestionable, that in early times it was exceedingly valuable, from the supposition of its being a rare and distinct metal, or particular species of copper; it being stated that as the mine in which it was obtained failed, it was supposed to be impossible to obtain it any other way, and that in value it held a middle place between gold and silver.

History of
brass.

After the real nature of brass became known in Europe, the Art of making it was principally confined to Germany, where the processes were kept very secret; and the first brass made in England was by persons of that nation, Jacob Momma and Daniel Demetrius, who, about the year 1649, established a brass work at Esher in Surrey, at a cost of £6000, but not meeting with encouragement, they were ruined by their undertaking, and the works were discontinued. Others, however, were afterwards established, and the operators employed English ore of zinc, which had been hitherto transported merely as ballast, but the copper was imported from Sweden till the revival of our own copper works in 1690.

The ore of zinc which is used in combination with copper to constitute brass, is called by the English calamine; it is of various colours, most commonly greyish with a cast of brown, a yellowish and a pale red. Some pieces are of

Ores of
zinc, their
colour, &c.

Manufac-
tures.

a gold yellow, others, white, blue, dark brown, &c. Several of the larger masses, when broken, exhibit all these colours, and in some places one colour, and in others a different colour is esteemed the best, so that mere colour seems to be little or no guide. England, Germany, and many other Countries afford calamine in great abundance: it is met with sometimes at considerable depths, and sometimes near the surface; in continued horizontal strata, in perpendicular veins, in detached masses bedded in different kind of earths, or intermingled with the ores of lead, and sometimes of other metals. It is plentiful in several lead mines in England, particularly about the Mendip hills near Wrington, in Somersetshire. Lead ores likewise frequently break up among the courses or strata of calamine. At Goslar, it is naturally intermixed, in very small molecularæ, with a compound ore containing lead, copper, and other metals; the zinc separates during the fusion of the ore, partly rising and running off in its metallic form into a reservoir made for this use, and partly subliming in flowers to the upper part of the furnace. Swedenborg informs us, that these flowers, called *cadmia* or *cadmia formacum*, are employed for the same purposes as the fossil calamine in other places, and that a less proportion of them is sufficient.

The English calamine is said to be found by the workmen to answer better than some which had been brought from Dantzick; by Margraff, to be richer in zinc than the foreign sorts which he examined; but Swedenborg states it to be of a worse quality than those of most other Countries, on account of its admixture with lead. When lead is combined with the ore, the larger masses are picked out by hand, and the smaller separated by washing. In this operation, the lighter parts are first washed away in the usual manner in an enclosure of boards by a stream of water passing through. The rest is then put into strong wire sieves, and well shaken in a vessel of water, by which means the more ponderous lead ores fall to the bottom and are thus separated; but where the lead ore is in too minute particles, or too intimately mixed to be separated by this process, upon calcining the mineral with a moderate fire, it runs into masses, which freely subside in the water from the purer calamine.

Method of
calcining
the ore.

It is customary to calcine all the sorts of calamine before they are employed for the making of brass. In some places the ore is piled in conical heaps of twelve feet diameter and six feet high, with layers of fuel intermixed. Such a pile burns about twenty-four hours. In other places the calcining is effected in a furnace built for the purpose, in which the ore is excluded from immediate contact with the fuel. In England, the calcining furnace resembles a baker's oven, with an apartment on one side for the fuel, wood or pit-coal; the partition betwixt the two chambers is open at top for suffering the flame to pass over and reverberate upon the mineral. The capacity of the furnace is such as to receive a ton of calamine spread four or five inches thick. The process lasts four, five, or six hours; the ore being occasionally stirred and turned with long iron rakes.

The marks of sufficient calcination are, the calamine being of a whitish colour, and easily reducible into a very fine powder. It loses in this operation from one-third to one-half its weight. A large quantity of flowers of divers colours is found adhering to the mouth of the furnace. These, though not applied to any considerable

use, appear to be the same with the *pompholyx* of the Ancients, and the celebrated *cadmia* of Goslar. It is stated that calamine not sufficiently calcined does not mix with copper; and that when over calcined, it makes the brass turn out brittle, and that it does not give the true tincture in either case. Swedenborg states, that the principal use of this process is, to render the calamine sufficiently pulverable; others state that calcination is never needful, unless where the mineral contains any sulphureous or arsenical matter.

The calcined calamine is next reduced to powder by iron mallets or by mills. In Sweden, it is said that the powder is ground between millstones in the same manner as corn.

The zinc contained in calamine is in a state of calx, and requires to be revived by the admixture of inflammable substances, in order to its uniting with copper. The inflammable matter generally made use of is charcoal. The harder sorts of charcoal are said to answer better for this use than the soft, occasioning the yield of zinc to be greater. The quantity of charcoal is usually equal to that of the calamine, but Cramer observes, that though an equal *weight* is necessary in small essays, in the larger works an equal *measure* is sufficient: the quantity of charcoal, on this supposition, is from one-sixth or a little less, to somewhat more than one-fourth of the calamine, according to their different gravities.

It is supposed necessary that the calamine and charcoal be reduced into very fine powder, especially the former, and that they be well mixed together. In some places, the mixture is performed by means of rakes drawn several times backwards and forwards through the powders, which are moistened with a little water or urine; in others, they are circumagitated together; at Goslar, a little alum and common salt are added, which are said to give the brass a better colour in the first fire.

It is also supposed necessary that the copper to be intermingled with the foregoing composition be pure and of a good quality, and that otherwise the zinc will not easily unite with it. Copper-plates have been generally made use of. These are stratified with the mixtures in large crucibles, a part of the mixture making the lower stratum, and of the copper the upper: the quantity of metal placed on the top, is double to that in the bottom of the crucible.

In some places the copper is reduced into grains, and uniformly mingled with the ore and charcoal; by this management it is said to gain an increase of one-tenth more than the plates usually do. The apparatus for granulating the copper is a brick cistern four or five feet deep, full of water, covered with a brass plate, in the middle of which is an aperture of half a foot. Into this is fitted a little vessel perforated with a number of very small holes secured with Stourbridge clay; the melted copper is poured into this vessel with iron ladles, and falling through the minute holes into the cold water, congeals into granules, without any explosion or danger to the bystanders. If the water is suffered to grow hot, the metal falls liquid to the bottom and runs into plates; to prevent this, a stream of cold water is kept continually passing through the cistern. The quantity of copper granulated at a time is one ton. Swedenborg, tom. iii. Ann. 1734.

The proportion of this calcined ore and copper for forming the brass varies in different works from 40 to 61. The two, combined in these proportions, are placed in crucibles made of Stourbridge clay, mixed

Mechanical
Processes.

Russia leather.

Manufactures.

Pl. xlv.
fig. 4.

with an equal quantity of the same clay calcined, or old pots powdered. Their capacity is such as to receive from 5 to 12 pounds of copper, with the requisite proportion of the calamine, and a furnace will receive several such crucibles. See plate xlv. fig. 4. The fire is at first gentle and increased by degrees till the metal comes into fusion, in which state it is kept for some time that the copper and zinc may be more perfectly united. To promote this effect, the crucibles are in some places occasionally shaken. The fire is continued from 9 to 16 hours, in most places 11 or 12. In Sweden, it has been found that with 14 hours the brass proves better than with 12. The fuel is applied twice, the first quantity being consumed in 9 hours, the other in 5 hours. In some works, if not in all, when the crucibles are put in the furnace, the spaces between them are filled up with damp fern, cut into cakes like hay from a rick, with which the crucibles likewise are covered. Above this are put two bushels of coal, and the furnace is covered with an iron plate a little way at first, and when the heat is strong, the whole way, a small quantity of coal is occasionally added and the clinkers are removed. The appearance of yellow fumes is a sign that the process is completed.

After sufficient fusion, the metal is lifted with its crucible by a pair of tongs formed for the purpose, and the brass in each is poured into one large crucible placed in the furnace to receive it; here it is carefully skimmed and afterwards cast into plates in moulds.

Description of the moulds. The mould consists of two flat stones enclosed in an iron frame joined at one side by a kind of hinge, with screws to raise or lower them occasionally. They are elevated at one end when the metal is to be poured betwixt them, that it may fill up the whole vacuity, and then they are set horizontally to cool.

These stones are about the size of grave-stones, and weigh each a ton or more. They must be annealed some hours before the plates are cast on them, otherwise the metal will fly and likewise endanger their breaking. In Sweden they are coated with clay; in England with coal and tallow. The workmen have many pair of them in readiness, because after three days' working they become *weary*, and require to be coated anew.

The stones most proper for this use are of the kind called *Saxa arenaria*. They have many small shining particles like spar which continue after long use. They should neither be very hard nor very soft; if too hard, they do not hold the clay, if too soft, they crack or shiver by the heat of the metal. The better sorts last four or five years.

The stones for this purpose are said to have been formerly imported to us from Holland and St. Maloes, but those now used are found in the mountainous parts of Cornwall. They are called in some places *Britain stones*, and are supposed to be the produce of this Country only.

Trials have been made at Hamburg and in Sweden, for substituting iron plates for the stones. The inconveniencies were, that the iron could not be coated with clay; that when not coated, the brass congealed without running to the further end of the mould; that it likewise proves porous and very brittle. Iron plates are nevertheless made use of in the Tyrol.

After the stones have been used for some time, their colour is changed from a grey to a reddish or copper hue, the shining specks only remaining. The crucibles are tinged throughout of a blue colour.

The plates of brass as first taken out of the mould are brittle, and in order to render them malleable, they must be annealed for some hours in an annealing furnace; the brass is then fit for the market.

The peculiarities of brass as compared with copper are, that it is lighter, harder, and more sonorous than pure copper. It melts more easily, but does not scorify so soon in a moderate heat. It is less ductile, and malleable only whilst cold. Heated a little, it cracks, ignited, it falls to pieces under the hammer, cooled in air at the ordinary temperature, it remains brittle as when hot, but cooled more slowly or annealed it becomes malleable; if heated beyond a cherry red, its zinc begins to exhale.

(595.) *Brass by cementation*.—Brass is generally made by fusion as described in the preceding part of this article, but it may also be obtained by cementation after a process similar to that by which iron is converted into steel.

This process is not, however, very generally understood. The following experiments, therefore, with which the writer has been furnished from the MSS. of an ingenious metallurgist, now no more, will be interesting.

The simplest kind of experimental cementing furnace for brass is one divided vertically by two partitions into three spaces, the fire being made in the two sides, and the metal, &c. deposited in the centre. This central part, although thus fixed in its place, is still denominated a crucible. The bottom of it is covered to about half an inch with powdered charcoal lightly pressed down. On this some copper in the form of bars or plates is laid, which is not intended to be converted into brass, and two large plates of copper are so placed as to line the sides of the crucible: the bars to be cemented or converted into brass are then placed in the middle. The crucible is then nearly filled up with a mixture of calamine and charcoal gently pressed down, but not very close, and then more powdered charcoal spread upon it; above this, thinner plates of copper are laid flat so as entirely to cover the materials, and two other large plates over them, and, lastly, the whole is covered with charcoal powder.

The following are the results of the several experiments alluded to.

Weight of Copper, Calamine, and Charcoal.

	lbs.	oz.	drs.

Mechanical Processes.

Brass formed by cementation.

Manufac-
tures.

A cover was luted on the crucible, having a hole in it to be opened occasionally for taking out the essay bars, and another into which a tube was inserted for allowing an exit to moisture and elastic vapours; a piece of copper was laid on the top of the pipe for discovering whether any flowers of zinc would arise.

A gentle fire was made in each of the side fire-places for about an hour to dry the luting, &c., after which a stronger fire, excited during the greater part of the time with bellows, was continued for eight hours, and then suffered gradually to decay.

Experiment 1.

At the end of the first two hours (exclusively of the hour of weak fire) the bar No. 1 was taken out. It appeared scarcely visibly red hot at the lower part, had undergone no sensible change, and had gained no increase of weight.

Experiment 2.

After two hours longer fire, the bar No. 2 was found red hot three-fourths of its length. The lower part was tinged externally yellow, and in breaking it the colour of the copper seemed in some measure gone off. Increase of weight barely 1 dw.

Experiment 3.

After two hours longer, the third bar appeared red hot all over; when cold, yellow externally to nearly the top. The calamine seemed to have penetrated quite into the middle, where it discovered itself in pale yellowish specks and streaks.

Increase of weight $1\frac{1}{2}$ drs. = about $\frac{1}{3}$.

Experiment 4.

After the fire had continued about two hours longer, and the whole had become cold, the furnace was uncharged. The two upper plates were found unchanged and scarcely sensibly increased in weight. All the others were in part tinged yellow externally and to a considerable depth.

	lbs.	oz.	drs.
Weights of the metal exclusively of the two upper plates and first essay bar.	Put in	9 11 12	
	Taken out.	10 3 6 $\frac{1}{2}$	
	Increase . . .	0 7 10 $\frac{1}{2}$	

Experiment 5.

Some of the pieces which appeared the most tinged, and which were externally of a very beautiful colour, in weight 6 ounces 13 drachms, were fused in a crucible with some charcoal powder. No sensible loss of weight. The metal appeared to the eye paler than common brass. On the rub-stone, it discovered more of a copper hue. It hammered well without cracking.

Experiment 6.

The rest of the copper with the two upper plates and bar No. 1, amounting in all to 10 pounds 7 ounces 12 drachms, was cemented a second time with the same mixture which now weighed 6 pounds 9 ounces 8 drachms = 105 $\frac{1}{2}$ ounces; 4 ounces more charcoal powder were mixed with it, and 2 other ounces were laid on the top. The two upper plates were turned upside down, the same side put next the crucible as before. The furnace was covered with its dome and chimney, and the

fire kept up 11 hours without blowing. After this second cementation, Mechanical Processes.

The metal weighed. . . . 10 lbs. 8 oz. increase 4 drs.

The mixture weighed. . . 6 lbs. 12 oz. loss 3 $\frac{1}{2}$ ozs.

Total increase 7 oz. 14 $\frac{1}{2}$ drs. = nearly $\frac{1}{18}$ calamine.

Examination in a blast furnace of the mixture remaining after the preceding cementation.

Experiment 1. (Perfect fusion.)

Upon 2 ounces of the mixture slightly pressed down, was laid 1 ounce of the twice-cemented metal in thin slips in a black lead crucible, which was filled up with charcoal in coarse powder and covered with a slip of brick. The metal was poured into a mould, some grains were collected by washing.

Weight of the whole 1 ounce 3 $\frac{1}{8}$ drachms.

Increase $\frac{7}{8}$ of the mixture or $\frac{7}{8}$ of the metal.

This experiment was repeated with the addition of 1 ounce more charcoal powder to the mixture, besides that on the top furnace which issued between the crucible and its cover: the charcoal seems to have burned away considerably; the increase was $\frac{1}{8}$ of a drachm less than before.

Experiment 2. (Imperfect fusion.)

The same was repeated in a crucible formerly used close luted. No fumes appeared; the metal melted imperfectly.

Increase of weight 2 $\frac{1}{2}$ drachms.

Experiment 3. (Perfect fusion.)

Four ounces of the metal were stratified with the same weight of the mixture mingled with 1 ounce fresh charcoal powder. The metal was melted with a pretty strong heat and poured into an ingot mould.

Increase of weight 13 drachms or $\frac{1}{8}$ of the metal.

Experiment 4. (Imperfect fusion.)

Mixture 4 ounces, metal 6 ounces. Great part of the mixture was put into the bottom of the crucible formerly used, and the copper slips laid thereon, with the rest of the matter intermixed. Fumes issued in considerable quantity, some of the slips melted, others did not, but just united.

Increase scarcely 13 drs. = $\frac{1}{8}$ of mixture.

Experiment 5. (Perfect fusion.)

Mixture 2 ounces metal, 4 ounces fresh charcoal, 1 ounce metal placed all on the top, with charcoal in pretty fine powder over it, close luted.

When the crucible came to a strong red heat, the cover was thrown off. Greatest part of the metal melted, so as to be poured into an ingot mould, which, with some grains collected by washing, weighed 4 oz. 5 $\frac{1}{2}$ drs.

Increase $\frac{1}{8}$ of mixture, or $\frac{5}{8}$ of metal.

(596.) *Proportion of the Component Parts in various Compound Metals.*

Gun metal 1 tin + 10 copper, or 1 tin + 2 zinc + 16 brass.

Bell metal. . . . 6 copper + 2 tin.

Specular metal. . . 7 copper + 3 zinc + 4 tin.

Bronze 7 copper + 3 zinc + 2 tin.

Bath metal. . . . 4 $\frac{1}{2}$ zinc + 16 brass.

Pinchbeck 16 zinc + 5 copper.

ditto 1 brass + 2 copper.

Princes metal. . . 3 copper + 1 zinc.

Manufactures.

Prince's metal . . 4 copper + 2 zinc.
 British tutania . . 4 copper + 4 tin + bismuth + 4 regulus of antimony to be combined with melted tin at discretion.
 Ditto 16 copper + 16 tin + 32 regulus of antimony.
 Queen's metal . . 9 tin + 1 bismuth + 1 antimony + 1 lead or 100 tin + 8 regulus antimony + bismuth + 4 copper.
 White metal . . . 10 lead + 6 bismuth + 4 regulus antimony or 10 tin + 8 brass + 2 regulus antimony.
 Hard white ditto, 2 brass + 3 zinc + 10 tin.
 Blanched copper, 16 copper + 1 neutral arsenical salt.
 Printer's types . . 10 lead + 2 antimony.
 Small type and } 9 lead + 2 antimony + 1 bismuth
 stereotype plates. } or 16 lead + 4 antimony + 1 tin.
 Common pewter, 7 tin + 1 lead + $\frac{3}{4}$ copper + $\frac{1}{8}$ zinc.
 Hard pewter . . . 12 tin + 1 regulus antimony + $\frac{1}{2}$ copper.
 Best pewter . . . 100 tin + 17 regulus antimony.
 Solder common . 2 lead + 1 tin.
 Ditto soft 1 lead + 2 tin.
 Do. for steel joints, 19 silver + 1 copper + 2 brass.
 Ditto silver . . . 19 silver + 1 copper + 10 brass.
 Ditto for plating, 1 brass + 2 silver.
 Ditto gold 12 pure gold + 2 silver + 4 copper.
 Standard silver, 37 silver + 3 copper.
 Ditto gold 11 gold + 1 copper.
 Jewellery gold . . $8\frac{3}{4}$ copper + $\frac{1}{2}$ silver + 1 gold.
 Common gold . . 3 copper + 1 old brass + $\frac{1}{4}$ tin.
 Menheim gold . . 7 copper + 3 brass + $1\frac{1}{2}$ tin.
 Gilding metal . . 4 copper + 1 brass + $3\frac{1}{2}$ tin.

Works for the Production of Acids, Salts, Pigments, and other Substances.

Alum Works.

Composition of alum.

(597.) The saline substance denominated alum by the Moderns is found by analysis to consist of

Sulphuric acid	34.33
Alumina	10.86
Potash	9.81
Water	45.00
	100.00

or, according to the atomic theory,

Sulphuric acid 4 + alumina 3 + soda 1 + water 25.

It is of extensive use in the Arts, particularly in dyeing, printing, and medicine.

History of alum.

This is not, however, the same substance which passed under the name of alum with the Ancients, the latter having been merely a vitriolic earth, formed naturally in some mines. Both alum and vitriol are neutral salts or saline substances, strongly resembling each other. Both contain the same acid; both have strong astringent qualities; they are both also frequently found in the same place, and obtained from the same mineral, and they both may be applied in the same manner and for like purposes. The difference is that vitriol is combined with a metallic earth, and alum with that of a white earth, called, therefore, alum earth.

The alum of the Ancients was a natural formation, and we, accordingly, find no account of alum and vitriol works in any Greek or Roman author, except what is mentioned by Pliny, who states that blue vitriol was

VOL. VII.

made in Spain by the process of boiling; and this circumstance he considers as the only one of its kind, and so singular, that he was of opinion no other salt could be obtained in the same manner. Besides, every thing related by the Ancients of their alum agrees perfectly with natural vitriolic substances; but to describe them all might be difficult; for they do not speak of pure crystals, but of saline bodies, which Nature herself exhibits in various ways, and under a variety of forms; and every small difference in the colour, the exterior or interior conformation, however accidental, provided it could be clearly distinguished, was to them sufficient to make a distinct species, and to induce them to give it a new name.

The celebrity which the ancient alum had, as a substance extremely useful in dyeing and medicine, was entirely forgotten when the alum of the Moderns became known; but this celebrity was again revived when it was discovered that real alum could be made from vitriolic minerals, or that where the latter are found there are generally minerals which abound with it. In many of these places alum works have, in the course of time, been erected; and this circumstance has served in some measure to give rise to the opinion that the alum of the Ancients and that of the Moderns are the same salt; because, where the former was found in ancient times, the latter has since been procured by a chemical process.

(598.) The first invention of the process of procuring the modern alum by artificial means is not known, but it appears to have originated in the East some time soon after the XIIth Century. In the XVth Century there were alum works in the neighbourhood of Constantinople, and about that period such works appear to have been first introduced into Italy and other Countries of Europe. The celebrated alum works of Tolfa, about six miles from Civita Vecchia, in the territories of the Pope, are stated by some Italian authors to be the first works of the kind established in Europe; and however this may be, they are the oldest carried on at present.

Here the ore is blown up with gunpowder: it is separated from the pieces of the rock that adhere to it; it is calcined in furnaces, nearly in the same manner as lime is burned; in six or seven hours being sufficiently calcined and friable, it is then taken out, and laid on pavements of a long shape, surrounded with walled trenches; on these it is laid in heaps of a moderate height, which are watered for forty days with water from the trenches. The ore being thus decomposed, it is boiled in large caldrons, and when the water is saturated to a certain point, it is poured into the crystallizing pans, where, after it is cold, it deposits the alum in large crystalline masses.

At Solfa terra, near Puzzuola, the alum is obtained by a different process, Nature herself assisting materially in the operation. Sulphurous fumes and sulphuric acid are continually issuing from little crevices in the volcanic soil of this place, the former of which deposit a concrete sulphur; the second gradually penetrates the ancient lavas, which are of an argillaceous nature, combines with their alumina, and thus forms an alum ore, which afterwards affords, by lixiviation and crystallization, a very pure alum.

The first alum works in England were established at Whitby in Yorkshire, by Sir Thomas Chaloner, who was excommunicated by Pope Pius II. for so doing, his Holiness having assumed the right of exclusively sup-

process as
described
by Mr.
Winter.

plying the alum of Europe. Notwithstanding this sentence, however, the work continued, and still continues to be the largest of the kind in England; there are, however, larger works, as the Hurlett mine near Glasgow.

Nearly all the alum works of Europe, with the exception of the two just mentioned in Italy, obtain the salt from pyritous ores. In the process followed in the latter cases the first step is the acidification of the sulphur, and the formation of the sulphate of alumina; to effect which the common practice is to roast the ore as soon as it is obtained from the mine. This is done by laying it in large heaps and burning it with wood or thorns till it is white, or it is sometimes done by rearing a pile of ore and of coal in alternate layers, and kindling it at the bottom. When it is sufficiently calcined, it is put into a pit, where it is macerated with water for eight or ten hours, the lie is then drawn off into large cisterns or reservoirs, and a fresh quantity of water is put on the ore in the pit. This, after some time, having acquired a sensible but weaker impregnation than the former, is likewise run off into the cistern. From this it is conveyed into pans, where it is kept boiling for twenty-four hours. There is then added to it a lie prepared from kelp; and after some time, the liquor is drawn off into a vessel, in which its impurities may subside. When clear, it is run into coolers, where it is allowed to remain four days and nights, and a quantity of putrid urine is sometimes added, in the proportion of eight gallons to a ton of liquor. When the alum crystallizes, the residual liquor is removed, and mixed with the liquor obtained from a fresh quantity of materials, which is to be evaporated. The crystallized alum is then washed, and the water allowed to drain from it; it is then melted in a pan, and while in its liquid state is conveyed into tuns, in which it is allowed to remain about ten days, during which it becomes fully concremented. The tuns are then unhooped, and the large masses of alum are broken down and stowed for market. A particular account of this process, observed at Whitby and other works, is given by Mr. Winter, in Nicholson's *Journal*, vol. xxv., from which it appears that the stratum of aluminous schistus impregnated with pyrites, in the Yorkshire district, is about twenty-nine miles in width, and is covered with strata of alluvial soil, sandstone, ironstone, shell, and clay. The alum schist is generally found disposed in horizontal laminæ. The upper part of the rock is most abundant in sulphur, so that a cubic yard taken from the top of the stratum is five times more valuable than the same bulk one hundred feet below.

(599.) According to Mr. Winter's statement, the expense of digging and removing to a distance of 200 yards one cubic yard of the schistose rock, is about sixpence halfpenny, and a man can earn from 2s. 6d. to 3s. a day. The rock broken into small pieces is laid on a horizontal bed of fuel, composed of brushwood, &c. When about four feet in height of the rock is piled on, fire is set to the bottom and fresh rock is continually poured upon the pile. This is continued until the calcined heap be raised to the height of 90 or 100 feet. Its horizontal area has also been progressively extended at the same time, till it forms a great bed nearly 200 feet square, having about 100,000 yards of solid measurement. The rapidity of the combustion is allayed by plastering up the crevices with small schist moistened; but notwithstanding this precaution, a great deal of sulphuric or sulphurous acid is dissipated. 130 tons of calcined

schist produce on an average one ton of alum. This result has been deducted from an average of 150,000 tons. Mechanical Processes.

The calcined mineral is digested in water contained in pits usually measuring about 60 cubic yards. The liquid is drawn off into cisterns, and afterwards pumped up again upon fresh calcined *mine*. This is repeated until the specific gravity becomes 1.5. The half-exhausted schist is then covered with water to take up the whole soluble matter. The strong liquor is drawn off into settling cisterns, in which the sulphate of lime, iron, and earth are deposited. At some works, the liquor is boiled, which aids in purification. It is then run into leaden pans ten feet long, four feet nine inches wide, two feet two inches deep at one end, and two feet eight inches at the other. This slope admits of their being easily emptied. Here the liquor is concentrated at a boiling heat. Every morning the pans are emptied into a settling cistern, and a solution of muriate of potash, either pretty pure from the manufacturer's, or crude and compound from the soap boiler's, is added. The quantity of muriate necessary is determined by a previous experiment in a basin, and is regulated for the workmen by the hydrometer. By this addition, the pan liquor, which had acquired a specific gravity of 1.4 or 1.5, is reduced to 1.35. After being allowed to settle for two hours, it is run off into the coolers to be crystallized. At a greater specific gravity than 1.35, the liquor, instead of crystallizing, would, when it cools, present us with a solid magma resembling grease. Urine is occasionally added to bring it down to the proper density.

After standing four days, the mother-waters are drained off, to be pumped into the pans on the succeeding day. The crystals of alum are washed into the tub and drained. They are then put into a lead pan with as much water as will make a saturated solution at the boiling point. Whenever this is effected, the solution is run off into casks. At the end of ten or sixteen days, the casks are unhooped and taken apart. The alum is found exteriorly in a solid cake, but in the interior cavity in large pyramidal crystals, inserted successively into one another. This last process is called *roching*. Mr. Winter says, that 22 tons of muriate of potash will produce 100 tons of alum, to which 31 tons of the black ashes of the soap boiler, or 73 of kelp, are equivalent. Where much iron exists in the alum ore, the alkaline muriate, by its decomposition, gives birth to an uncrySTALLIZABLE muriate of iron.

The alum manufactured according to the preceding mode is a sulphate of alumina and potash. There is another alum which exactly resembles it; this is a sulphate of alumina and ammonia. Both crystallize in regular octoedrons, formed by two four-sided pyramids joined base to base. Alum has an astringent, sweetish taste. Its specific gravity is about 1.71. It reddens the vegetable blues. It is soluble in 16 parts of water at 60°, and three-fourths of its weight at 212°. It effloresces superficially on exposure to air, but the interior remains long unchanged. Its water of crystallization is sufficient at a gentle heat to fuse it. If the heat be increased, it froths up and loses fully 45 per cent. of its weight in water. The spongy residue is called burned or calcined alum, and is used by surgeons as a mild escharotic. A violent heat separates a great portion of its acid.

Mr. Winter is very averse from the use of urine in this manufactory, observing that at the works of Lord Dundas, and those of Messrs. Baker and Co., which approach

Manufac-
tures.

nearest in their process to true chemical principles, they use no urine. The alum liquor is always purified previous to its being used. They use no alkali generally, but crystallized muriate of potash; greater economy is observed in the consumption of fuel, and the result is a product of alum considerably larger in a given time, and of better quality than can be produced on the old plan.

The kelp used is obtained by burning the sea wrack in kilns, at a great many places on the coast of England, Scotland, &c., but it is a very inferior alkali in an alum manufactory; it contains about 47 of soluble salts, and 53 charcoal, sand, and dirt; the salts are muriate of soda and sulphate of soda. The refuse of soap boiler's lees are burned in a kind of oven, and sold under the name of black ashes. The composition of these ashes is about 90 soluble salts and 10 of charcoal and earths. The salts contain muriate of soda and potash, sulphate of potash, and muriate of lime and magnesia. Mr. Winter says he always found great difficulty in producing alum by the muriate of soda, and never could form alum in any way by means of pure soda. The muriate and sulphate of potash are the only alkalis that can be used to advantage in the composition of alum.

The following are the results of Mr. Winter's experiments on the quantity of different alkalis required to make 100 tons of alum; viz.

22 tons of muriate of potash, 100 tons alum.

31 ditto black ashes ditto.

70 ditto kelp ditto.

Nicholson's *Journal*, vol. xxv.

In 1828, Mr. Strachan took out a patent for an improvement in the method of manufacturing alum, for a description of which we refer the reader to vol. liv. of the *Repertory of Arts*.

Charcoal Works.

Manufac-
ture of
charcoal.

(600) Charcoal, as an important article in many processes connected both with the Arts and Manufactures, may, it is presumed, be with propriety introduced into this section of the Treatise, although the place of manufacture or preparation of it is not generally called a charcoal work.

For common purposes the usual way of charring wood is in what are called *charring pits*. The wood is first cut into lengths of about three feet, and then piled on the ground in a circular form; three, four, or more faggots, or, as they are called, cords of wood, making what is called a pit. These are covered with fern, straw, &c., or kept down by earth or sand to support the fire, giving it air by vent holes as may be found necessary or convenient; but this mode of charring is uncertain in its operation, and in every respect defective for the purpose of making good charcoal, and, consequently, it is when thus prepared very unfit for the manufacture of gunpowder, which requires all its ingredients to be of the most perfect kind.

For the latter purpose, therefore, in particular, the method now adopted consists in distilling the wood in iron cylinders, not much unlike the method practised in our gas works for the distillation of the coal. For this purpose, iron cylinders or retorts are employed, and the wood to be charred is cut into pieces of about nine inches in length, and then put into the cylinder, which is placed horizontally. The front opening or mouth of the retort is then closed, and at the further end are pipes leading into casks. The fire being made under the

cylinder in the proper furnace, the pyroligneous acid, attended with a large portion of carburetted hydrogen gas, comes over. The gas escapes while the liquor descends through the pipes, and is collected in the casks, and the fire is kept up till no more liquor or gas will come over. This, it is evident, is a more eligible method than the former, indeed the only proper one, and the difference in the strength of powder made from the two sorts of charcoal is such, that since the Government powder has been made with it, the charges of powder for the same piece of ordnance are said to have been reduced one-third. We suspect, however, that some of this reduction is due to the more accurate boring of the gun, the gauging of the ball, and the resulting reduction of windage. It should be remarked, that the wood before charring has its bark taken off; and for this reason it is best felled in the Summer season, when the sap is up, and will admit of the bark being more easily and cleanly removed. One reason for taking off the bark is, that powder, into which the burned bark enters, is full of sparks, which is, of course, both injurious and dangerous.

The wood made use of is commonly elder, willow, or black-dog wood, and these are said to be very superior for the purpose in the old way of charring, although there are some differences in opinion on this point; but it is generally admitted, that in distilling in cylinders as above described, the particular nature of the wood is by no means important.

Indigo Works.

(601.) Although the preparation of indigo can have no claim to be considered as a British process, yet as it is so important to the art of dyeing, printing, &c. in this Country, and is principally derived from our foreign dependencies, and, moreover, the operation itself being very interesting, we do not hesitate to include indigo works amongst the general list of those which relate to the preparation of various substances of a similar class employed in the Arts and Manufactures of Great Britain.

Indigo, the most important of the vegetable colours used in dyeing, unlike logwood, madder, and most other colours, is extracted from the tree or shrub which contains it, before it arrives in this Country. It is usually imported into Great Britain from the West Indies and America; it is also made in the East Indies, where its cultivation has latterly been much encouraged.

Indigo, or its basis, is contained in the *Isatis tinctoria* which grows in temperate climates, and in some leguminous plants of warmer latitudes, particularly various species of the *Indigofera*. The plants from which our indigo is usually produced are, 1. *Indigofera anil*, a large American plant, which affords indigo of good quality. 2. *Indigofera tinctoria*, a Chinese and Indian plant, which has been carried to America; this is less hardy but more productive than the preceding. 3. *Indigofera disperma*, which affords the Guatemala indigo; its produce is uncommonly fine, but not abundant. 4. *Indigofera argentia*, which produces the indigo bastard of the French; and, 5. *Nerium tinctoria*, from which the East Indian indigo is now produced.

(602.) *History of indigo*.—Considerable uncertainty seems to exist about the early history of indigo, which probably arises from the circumstance of all Indian productions having been brought at that time over land, or

Manufac-
tures.

partly by the Persian Gulf and partly by land to Babylon, or through Arabia and up the Red Sea to Egypt, from which it was transported to Europe. Considering this long carriage, and that the article was not obtained in a direct manner, it is not surprising that our knowledge with respect to its actual Country and the manner of preparing it should be very uncertain and imperfect.

It is the opinion of most authors that the substance termed by Dioscorides *indicon*, and by Pliny and Vitruvius *indicum*, is the same as our present indigo. It is described as a blue pigment brought from India, and used both in painting and dyeing. When pounded it gave a black powder, and when diluted in water produced an agreeable mixture of blue and purple.

Indigo seems to have been mentioned by the Arabian Physicians, and Muratori gives a Treaty written in Latin, of the year 1193, between the citizens of Bologna and Ferrara, which contains a list of those articles subject to pay duty, among which occurs *indicum*. In the XIIIth Century the celebrated Marco Polo, who spent twenty-six years in travelling through Asia, and even some parts of China, relates, that he saw indigo, which the dyers used, made in the Kingdom of Coulan or Coilum, and he describes the process of preparing it.

Much curious information with respect to the trade in this article in the middle of the XIVth Century is contained in the valuable Works of Francesco Balducci Pegolotti. We there find the names of different kinds made use of at that time; such as *Indaco di Buldacca*, detto *buccaddeo*, in all probability from Bagdad, a city which, in many old books of travels, is called Baldach, or Buldac, also *Indaco del Golfo*, *Indaco di Cipri*, &c. Indigo, at that time, was imported in hides (*cuojo*) or in leathern bags (*otre*.) Nicolo Conti, who travelled through India before the year 1444, mentions *endego* among the merchandise of Camboia.

The first Portuguese ship returned from the East Indies in the year 1499, and was soon followed by others laden with the most valuable merchandise of the East. Beckmann, in his *History of Inventions*, states, that he was never able to obtain the invoice of the cargoes of these vessels, but has no doubt that indigo was among the first articles.

Barbosa, a Portuguese who collected in 1516 valuable information with respect to Geography and Trade, who afterwards accompanied Magellan in his voyage round the world, and perished with him at the Island of Zebu, has given a price current of the merchandise at Calicut, in which the value of good indigo at that time is stated. Corsali, also, in his letters written from India in the same year, mentions indigo among the wares of Camboia.

Niska, who wrote in 1630, says indigo had been introduced into Germany only thirty years; and an order of the Emperor Ferdinand III., dated 1654, says, that it had been imported into Germany from Holland some years before that period. That the importation at this time was very great is proved by the cargoes of the ships which arrived in Holland from the East Indies in 1631. The first had 13,539 pounds of Sirches indigo; the second 82,734 pounds of Guzerat indigo; the third 66,986 pounds of the same; the fourth 50,795 pounds of Bejana indigo; the fifth 32,251 pounds of Chirches indigo; the sixth 59,698 pounds of Bejana indigo; and the seventh 27,532 pounds of Chirches. These seven vessels, therefore, brought to Europe 333,545 pounds of

indigo, which at a low valuation were worth 500,000 dollars. Mechanical Processes.

The profit attending this trade induced people soon after the discovery of America to manufacture indigo in that Country; and they were the more encouraged to do so by observing that the native Americans, before they became known to the Christians, tinged their bodies and faces of a blue-violet colour, by means of indigenous plants, which resembled the indigo plant of Asia.

Whether the two plants are of the same genus, and whether the American is different from that used in other quarters of the Globe, does not seem to have been with certainty determined. It is, however, proved, that the assertion of Raynal and others, of this plant being first conveyed to the New World from Asia by Europeans, is entirely erroneous. It is mentioned by Francis Colon, in the life of his father, among the valuable productions of the Island of Hispaniola or St. Domingo. Francis Hernâdes reckons it among the natural plants of Mexico, and says that the Americans used it for dyeing their hair black. He adds that they made it from a pigment which they named Mohuilli and Tleuohuilli, the same as the Latins named *cæruleum*, and he describes also the method of preparing it. This is confirmed by Clavigero, who published an account of Mexico.

This plant must therefore be reckoned among the few which are indigenous in three quarters of the Globe. It is, however, highly probable that the Europeans in the course of time introduced a better species or variety in America, where several kinds are cultivated at present.

The indigo was now brought from both the Indies to Europe, and was found so superior in the richness of its dye, the facility with which it could be used, and other advantages attending it, that it suddenly banished from all dye-houses the European woad, which was cultivated in particular in Thuringia, in Germany, in Languedoc, in France, and in the neighbourhood of Rieti in the dominions of the Church. At first, only a small quantity of indigo was added to the woad, by which the latter was much improved; more was afterwards gradually used, and at last the quantity became so large, that the small admixture of woad served only to revive the fermentation of the indigo. Germany thus lost a production by which farmers, merchants, carriers, and others acquired great riches. In consequence of the sale of woad being so much injured, a prohibition was issued against the use of indigo by Saxony, in the year 1650. In the year 1652, Duke Ernest the Pious caused a proposal to be made to the Diet by his envoy, Dr. Hænnen, that indigo should be entirely banished from the Empire, and that an exclusive privilege should be granted to those who dyed with woad. This was followed by an Imperial prohibition of indigo on the 21st of April, 1654, which was enforced with the greatest severity in his dominions. What was done in Germany with regard to Thuringia was done in France with regard to Languedoc. In consequence of an urgent representation of the States of that Province, the use of indigo was forbidden in 1598, and this prohibition was afterwards repeated several times. But in the well-known Edict of 1669, in which Colbert separated the fine from the common dyers, it was stated that indigo should be used without woad; and in 1737 dyers were left at liberty to use indigo alone, or to employ a mixture of indigo and woad.

Manufac-
tures.

In England, where, at that time, it appears that woad was not cultivated, the first mention of indigo in the laws occurs in the year 1581, under the reign of Elizabeth; not, however, on account of a blue but a black dye. No woollen cloths were to be dyed black with the nutgall, madder, and other materials, till they had received the first ground, or been rendered blue by woad, or woad and indigo together; the consequence of which law was an increase in the consumption of indigo; and from that time the use of indigo has gradually increased in this Country, and now forms a very important article of commerce, producing a revenue of upwards of £30,000 per annum.

Culture of
indigo.

(603.) *Culture of indigo.*—In the cultivation of this plant, one of the most important points to be attended to is, to have the ground thoroughly drained and cleared from weeds. The soil should be fine and rich, and the climate warm; and the season of sowing should be rainy, as the earth must either already have imbibed water, or rain must speedily follow the sowing, otherwise the seed becomes heated and rots, and all the labour spent upon it is of course lost. The ground being prepared, a number of slaves ranged in a line march across making little trenches of the width of their hoes, and two or three inches deep, and about a foot distant from one another every way; then returning, they drop some seeds in each trench, and afterwards cover them with the earth taken out.

During the process of vegetation the ground must be carefully weeded, in order to prevent any mixture of herbs, which would injure the indigo in its manufacture. In moist weather the plant comes up in two or three days, and in about two or three months after it is fit for cutting. If suffered to run until it runs into flower, the leaves become too dry and hard, and the indigo obtained from them proves less in quantity and less beautiful: the due point of maturity is known by the leaves beginning to grow less supple or more brittle. In rainy seasons, the cutting may be repeated every six weeks: cutting in dry weather kills the plant; but if that is avoided, one plant will continue to afford fresh crops for two years.

The manner in which it is commonly prepared is as follows: a large quantity of the herb is put into a vat or cistern of strong mason-work, with so much water as is sufficient to cover it, and some wood is laid above to prevent it rising up. The matter begins to ferment sooner or later, according to the warmth of the weather and the maturity of the plant, sometimes in six or eight hours, and sometimes in not less than twenty. The liquor then grows hot, throws up a plentiful froth, thickens by degrees, and acquires a blue colour, inclining to violet, and in proportion as the heat increases, azote is disengaged, the vegetable is decomposed, and the mixture absorbs oxygen; the fermenting fluid passes from a green to a violet tinge, and this by degrees changes to a blue colour. The great art of the manufacturer is to check the fermentation at a proper degree; for if it is checked too soon, the plant remains impregnated with much essential salt, which diminishes the quantity of indigo; and if allowed to remain too long, the tender extremities of the plant undergo a putrefaction which destroys the beauty of the colour. Some years ago, a method of invariably ascertaining the correct fermentation of the indigo was published at St. Domingo, which consisted in writing on white paper with the matter to be examined, and if the ink be of a very

high colour it is a proof that the fermentation has not arrived at its true point. The experiment is repeated every quarter of an hour, until it is perceived that the liquid has lost its colour, which is said to be a very correct method of ascertaining the proper degree of fermentation. Others pour a quantity of the liquid into a silver cup, which they shake until the grains are deposited, and judge by the quality of them the proper state of fermentation. When the feculent particles begin to be precipitated to the bottom of the cup, it is then judged that the herbs have attained the true degree of maceration to obtain indigo. Five or six minutes after the liquid has been put into the cup, it is perceived to form round its edges a cordon of feculæ or sediment, at first of a green colour and then blue. When the maceration is not at the requisite point, the cordon or girdle detaches itself with difficulty from the sides of the cup, but finally precipitates, and the water above it becomes limpid, although of a yellowish hue. When these signs are perceived, they infallibly indicate the success of the first operation.

The liquid impregnated with the tincture is then let off by cocks in the bottom of the vessel into another vat placed for that purpose, without disturbing the herb.

In the second vat the liquid is strongly and incessantly beaten and agitated with a kind of bucket fixed to a pole, until the colouring matter is united into a body. A good deal of nicety is required in this operation also, for if the beating ceases too soon, a part of the colouring matter remains dissolved in the liquid; and, if continued too long, a part of that which had separated is dissolved afresh. The exact time for discontinuing the process is determined by taking up some of the liquor occasionally in a little cup, and observing whether the blue fecula is disposed to separate and subside.

The whole being now suffered to rest until the blue matter has settled, the clear water is let off by cocks at different heights in the sides of the vat, and the blue part discharged into another vat by the cock at the bottom. Here it is suffered to settle for some time longer, then further drained in cloth bags or sacks, and exposed in shallow, wooden boxes to the air, without admitting the sun, and carefully keeping it from the rain till thoroughly dry.

Before it is quite dry, it is cut into small pieces of an inch square, which may be detached readily from the box when it is quite dry. Yet, however well dried and drained the indigo may be, it always experiences in the first month of its fabrication a considerable diminution of quantity. It is packed for commerce either in barrels or in sacks of coarse linen, covered with ox-hides, so perfectly sewed together as entirely to exclude the air. These packets are called "ceroons;" they are much preferable to barrels, as they are more solid and more conveniently transported from one place to another.

Indigo is commonly divided, from the colour it exhibits when broken, into three kinds, viz. copper-coloured, purple, and blue. These different appearances probably depend upon the different methods of preparing the indigo used by different manufacturers, upon the age of the plant, which greatly influences the appearance of the indigo, or upon the time at which the plant is gathered. The superiority of some of the indigoes of the East Indies over those of America is said to proceed from the leaves of the plant being alone employed and the twig thrown away. Some heat the water in the steeping

Dr. Rox-
burgh's
description
of the tree.

vat with a view to increase the quantity extracted, but this is considered to debase the quality of the indigo, by the substance of the leaves and the bark becoming blended in water with the colouring matter.

(604.) We add the following account of the tree, and the method of preparing the Nerium indigo, extracted from a communication from Dr. William Roxburgh of Calcutta to the Society of Arts.

The tree from which this indigo is obtained is elegant in form and middle-sized, perfectly agreeing in character with the genus *Nerium* of the Linnæan sexual system. The trunk is short and erect, and in large trees reaches the size of one foot six inches or two feet in diameter. Its height when full grown varies from twenty to thirty feet. The wood is white, close-grained, and very beautiful, approaching the colour and appearance of ivory. The leaves are numerous, of a pale green colour, pointed, and of an oblong shape; when full grown from six to ten inches long, and from three to four broad.

This, with a variety of it with leaves considerably longer and narrower, and somewhat downy, which also yields indigo, but of an inferior quality and less in proportion, are natives of the hills and lower regions of the mountains directly North from Coringa, in the Rajah-Mundry-Circar, and delight most in the South and sunny side of these hills and mountains. It also grows in similar places in other parts of the Circars and in the Carnatic, being an extent of country of more than one thousand miles in length.

To cause the trees to yield a large supply of the best leaves for making indigo, it is necessary to keep them low as found in the vicinity of the habitations of the natives, by cropping off the branches, which causes many shoots to issue from the cut stumps. These in one year acquire various heights of from one to ten feet, according to the nature of the soil, and yield a great quantity of leaves.

The leaves begin to be fit for making indigo in the month of April, but in May and June, which is the hottest time of the year, are found to yield a better colour than in any other month. About the end of August, the growth of the plant begins to draw to a close for the season: the leaves acquiring a yellowish-rusty hue soon fall off, without being succeeded by others, or in a trifling degree until next season; so that with the plants in a wild state, which is the state alluded to in these observations, the length of the season for making indigo can only be reckoned at from four, or at most five months of the year.

Dr. Roxburgh tried the leaves of some plants raised from seed in his garden, but found they did not yield colour until several years old, and then but in a trifling degree, and of a quality inferior to that which the wild plants afford in their natural soil; and he remarks that it is the same with the young plantations in Bengal. If the leaves are culled and only the best chosen, the indigo is considerably more beautiful than when taken promiscuously with the extremities of the branches, when some (the lowermost on the shoots) will be rather too old, some at the extremity too young, and those of the middle part only of a proper age. He could never extract any thing like blue indigo from the tender shoots of this plant when deprived of their leaves, which is not the case with the twigs of the common indigo plant, which when totally deprived of its leaves will yield a tolerably good indigo, although inferior to that produced by the same process from the leaves alone.

The author made several experiments, because he considered it of importance to determine this point, that care might be taken to prevent the labourers from plucking the twigs, which they will always do if not strictly watched, because they can fill a basket or measure much sooner if permitted to bring them along with the leaves. Manufacturers of the *Nerium* indigo require to attend to this, otherwise they will gather the twigs with the leaves upon them, which will both diminish the produce of indigo and debase its quality.

The leaves, when collected in sufficient quantity, are put into the copper, so as to fill the vessel without being pressed down, and then the vessels are filled with cold water to within three or four inches of the top. This space is required to be left, because the bulk enlarges by heat as much as the common indigo vat does by fermentation. Dr. Roxburgh tried different kinds of water, viz. rain water, soft water from wells and from a river, and various kinds of hard water, and found the hard water to give the best indigo, and in the largest proportion.

The fire is then lighted, which must be maintained rather briskly until the liquor acquires a deep green colour when viewed in the vessel; but if taken up and poured from one vessel to another, a pale but bright greenish-yellow; the leaves will then begin to assume a yellowish colour, and the heat of the liquor will be about 150 or 160 degrees of Fahrenheit's scale. The leaves must be constantly agitated and turned upside down to produce as nearly as possible an equal degree of scalding, if not, those at the bottom would be much overdone before those at the surface were ready. The motion answers another purpose; it serves to expel the fixed air which greatly forwards the operation. The fire must be withdrawn or suffered to die away some little time before the liquor has acquired the above-mentioned appearance; and it is necessary to have all the different vessels that are to be let into the same agitation-vat ready at the same time. When they are ready, the whole is drawn off at once. A contrivance must be had recourse to to let the liquor pass through a hair-cloth, (a coarse *comly*, such as the poorer classes of the natives wear in cold weather, answers perfectly well,) to prevent any of the leaves, &c. from getting into the agitation-vat. As soon as the whole is run off, it must be, while hot, agitated in the common way for some minutes; from five to twenty will generally be found sufficient to produce the necessary degree of granulation. About from one-seventieth to one-hundredth part of strong pure lime water is then let in from the lime-water cistern, the liquor being still hot, which requires only to be sufficiently mixed with the liquor to produce quickly a very large grain which soon precipitates. The supernatant liquor is then let off, and the rest of the process is the same as is employed in making the common fermented indigo.

If the process has been properly conducted, the supernatant liquor will run off of a clear Madeira-wine colour, which is a sign that it retains none of the indigo. The produce of the indigo when dry will average about one pound for every two hundred and fifty pounds of green leaves, but varies according to the season and state of the weather when gathered. Dr. Roxburgh found that by the end of August or September they would not yield much more than one-half or two-thirds of the quantity which they give in May or June, and even that is diminished if the weather be wet, or if the leaves are committed to the fire immediately after they have been gathered.

Mechanical
Processes.

Manufac-
tures.

The operation is performed with ease twice a day ; it may be performed three times. The scalding to the degree already mentioned requiring only about three hours and the agitation and precipitation not more ; so that by the time the scalding is completed, the fecula of the preceding operation is ready to be removed from the large agitation-vat into the small cistern, where it is to remain until the fecula has precipitated into a still smaller bulk. The supernatant liquor is then let off by scuppers, and the fecula is put into bags to drain.

M. de Cossigny, in his *Treatise on the Cultivation and Manufacture of Indigo*, observes, that it is much improved if the moist fecula is washed with warm water, in which a small quantity of acid of vitriol has been mixed ; this Dr. Roxburgh also considers to improve the Nerium indigo. A small quantity will suffice. The use of the acid seems to be to dissolve any remains of the calcareous precipitant, or other extraneous matter that may unavoidably be mixed with the fecula ; all of which ought to be further washed off by several subsequent washings with pure water, which is the better for being hot.

Description
of an indi-
go work.
Pl. xlvii.

(605.) A plan, section, and perspective view of the apparatus used in the Nerium indigo manufacture is shown in plate xlvii. where fig. 1 is a perspective view ; fig. 2, a plan taken at the iron bars or grating which support the coppers ; fig. 3, 4 a longitudinal and transverse section to exhibit the internal structure of the works. The same letters refer to all the figures.

A is a cistern for holding water in readiness to fill the coppers ; it is fifteen feet square and three feet deep ; *a* is the channel for conducting the water from the cistern into the coppers, which is about two inches above the bottom to allow the impurities to settle ; *b* is a channel by which the impure parts of the liquor are occasionally drawn off for the cistern to be cleaned.

To raise the water to fill the cistern is an object of much consequence ; in several places amongst the hills where the Nerium grows there are little rills of water running upon such a descent as to render it only necessary to construct the works on some low adjacent spot, that the water may be conducted with little trouble into the cistern. When no such supply of water can be had, pecotahs, or a chain pump made of four boards, as described in our hydraulic engines, article 340, *et seq.*, may be used, or if the water is very low, it may be done by the funnel-like leather bucket shown in the figure, which is wrought by a pair of buffaloes or bullocks. To the mouth of the tube or pipe of this leather funnel bucket, (see fig. 1,) is fastened a cord *a*, which leads over a roller placed at least the length of the body of the bucket below the wheel V. The bucket is raised by two ropes, one of which raises the body of the bucket, and the other the funnel end of the same. The cord *a* which supports the funnel end of the bucket is of such a length as to keep the mouth of the funnel rather above the square mouth until it reaches the roller, when the end passes into the trough while the body of the bucket continues to ascend until the bottom is above the level of the trough, by which time the whole of the water will have made its escape. This method of raising a large quantity of water from a great depth is in common use over many parts of Hindostan, where the wells are too deep for the use of the pecotah or lever. It is of great advantage to have the water in readiness in this manner, for it not only forwards the work much, but also gives time for any impurities to settle at the

bottom. In the perspective view the cistern A is omitted to show the other parts of the work on a larger scale.

B are the coppers or scalding vessels resting on the grate *c*, which is supported by the walls and by the pillar *d* ; they are made to communicate with each other by the openings *e* ; *f* is the top of the walls which surround the vessels ; they are made two or three inches lower than the edge of the coppers to prevent dust getting in, and sufficiently broad for the workman to walk about upon to attend the work ; *n* are the fire-places. C, the agitation-vat or beater, twenty feet square and three deep, one foot of which may be called the border, being made thinner ; it prevents the dust and dirt getting in from the feet of the workmen while walking about to agitate the liquor, &c. ; *h* are two scuppers for letting off the clear supernatant liquor from the fecula ; *i* another by which the fecula is drawn off ; D the lime-water cistern, which may be made with a border and lid to exclude the air or arched ; it has an opening at the top to put lime and water in at, and for a boy to go in to clean it ; the closer this can be shut, the better the lime water will be ; *k* the scupper for letting the lime water into the agitation vat.

E the small fecula cistern for the fecula to further settle in ; *l* the scuppers to let off the supernatant liquor, over which the bags are hung until the liquor drops clear of them.

The transverse section, fig. 4, is upon a larger scale than the former. It is made through the middle of one of the coppers F, and through the middle of one of the arched openings *m* which serve to feed the fire. This shows the channel G for carrying the scalded liquor from the boilers to the agitation-vat C, fig. 2, 4 ; it is supported by four beams extended between the abutments ; *n* is one of the scuppers, by which the liquor runs from the coppers to the channel G ; *d d* are pillars which support the square bars of iron of the grate ; *q* the opening which communicates with the next copper. To prevent any leakage at these communications, and to be able to separate the vessels, Dr. Roxburgh suggested the following contrivance ; it is represented in fig. 4. Holes are made in the sides of the two contiguous coppers corresponding with the four screws. A thick square piece of welted hide, with a square hole corresponding with the holes in the sides of the vessels, is slipped in between them, and the two plates of iron shown in fig. 5 are placed one in each copper, and screwed very tight together.

Fig. 6 are two beaters, each being a square-headed churn-staff, which answers exceedingly well to turn the leaves while scalding, and afterwards to agitate the liquor with ; four of them are found sufficient for an ordinary vat. If workmen for joining the sheathing can be had where works are to be erected, Dr. Roxburgh considers it would be a saving of copper, and otherwise more convenient, to have only one vessel : the length may be made as much as may be necessary for the quantity of leaves that may grow in the vicinity of the place. If constructed in this manner, there will be no need of the channel G in front of the vessels : one large scupper from the end of the vessel next the agitation-vat is all that is thus necessary ; the other parts may remain as above mentioned.

Dr. Roxburgh afterwards joined the above-mentioned six vessels into one, by cutting out the divisions and joining them upon the grate : with the copper so got out from the sides, he lengthened the now single vessel

Mechanica
Processes.

Manufac-
tures.

to more than forty feet. This required ten additional fire-places, as a fire was necessary to every five feet of length when the vessel is ten feet broad, which is a surface of fifty square feet for each fire to act upon. *Transactions of the Society of Arts*, vol. xxviii.

Litharge.

(606.) This is an oxide of lead, made by the simple action of heat and air on the metal; it is produced in the process of extracting silver from lead, and has been already explained under the latter head.

Minium or Red Lead Works.

Red lead.

(607.) The process of making red lead in Derbyshire is described by Dr. Watson in his *Chemical Essays*, vol. iii. as follows. The furnace is much like a baker's oven with a low vaulted roof, and on each side of the furnace are two party walls rising from the floor of the furnace, but not reaching to the roof. In the interval between these walls and the sides of the furnace the coal is burned, and the flame, drawn over the top of the party wall and striking against the roof, is thence reflected down upon the surface of a quantity of lead which is laid on the floor of the furnace. The metal soon melts, and instantly becomes covered with a pellicle which is successively raked off till the whole is changed into a greenish-yellow powder. This is taken out, ground in a mill, and washed, to separate the portion of lead that still remains in the metallic state, by which it becomes a uniform yellow colour, and is then thrown back into the furnace and constantly stirred, so that every part may be equally exposed to the action of the flame, and after about forty-eight hours of calcination it is converted into red lead.

Some practical nicety is required in the management of the fire, which, if too slack, gives only a yellow or orange-coloured powder, and, if too fierce, makes the minium dusky, and destroys that brilliant gloss for which it is so much admired. There are besides other minuter circumstances of management, and probably kept secret as much as possible. Jar mentions in particular that of cooling the minium very gradually, and closing all the openings of the furnace, otherwise, he says, the beauty of the colour is much impaired.

Ceruse or White Lead Works.

White lead.

(608.) This is a carbonate of lead prepared in the first part of the process of making the acetate of lead. First, lead is melted and cast in a case or mould, so as to form a sheet of about 2 feet 5 inches broad, and from one-sixteenth to one fourth of an inch thick. The lead in this instance is cast at once of the proper form, and not mechanically flattened like sheet lead, that its texture may be more open, and more easily penetrated by the acid vapour. These plates are then rolled up into a loose coil, and each is placed perpendicularly in an earthen pot, like a common garden pot, holding from two to six pints each, but with a ledge on the inside about half way down, on which the coil of lead rests, so that it may not touch the bottom. Each pot is filled with vinegar of any kind, just so high as not to wet the bottom of the lead, and the whole is also covered with a plate of lead fitted very close. The pots are then ranged under a building, so as to shelter them from the weather, and buried pretty deep in fresh stable litter or tanner's bark, layer upon layer,

according to the number of pots. The heat of the dung soon fills the upper part of the pots with the vapour of the vinegar below, and the lead kept constantly in contact with the acid vapour, but not immersed in the liquor, presently begins to corrode and oxidate at the surface. The pots remain under the litter for about two months, at the end of which time they are taken out and the coils of lead are found deeply corroded, and the surface converted into a whitish, scaly, brittle oxide. This is separated by passing the plates between rollers, which causes it to peel off, leaving the lead beneath in the metallic state. This oxide is then mixed with a little water, and passed between a pair of mill-stones; then the finer parts are separated from the coarser by successive washings, the former being longer suspended in water than the latter, till the whole of the finer oxide is obtained. This is then dried either in the air or in large airy rooms, warmed by a small stove, and is then perfect ceruse or white lead fit for use. Of late years the scales of oxide, instead of being separated from the coils by dry laminating, which raised a dust of lead highly injurious to the health of the people about them, are detached by spreading the coils upon a perforated wooden floor covered with water, and drawing them to and fro by rakes, which detaches the oxide, and causes it to sink through the water and the holes of the floor to the bottom of the vessel below. *Aikin's Dictionary*.

Acetate or Sugar of Lead Works.

(609.) Sugar of lead is used very largely in various manufactories of this Kingdom, particularly in calico printing, and the works for preparing it, although very simple, are confined to very few places. Most of the sugar of lead used in this Country is imported from Holland. This salt is made very nearly in the manner of ceruse; that is, lead sheets are put into pots with vinegar, and digested a sufficient time, but here the vinegar is distilled, and the plates, instead of being entirely out of the liquor, are half immersed in it. This being done, the upper half is soon covered with an efflorescence of ceruse, after which it is immersed in vinegar, and the part which was before immersed is now brought up to be converted into ceruse as before, when the plate is again turned, and the newly oxidated surface in its turn immersed in the liquor. The plates are thus turned about two or three times a day, and the vinegar in saturating itself with the ceruse becomes milky, and soon sufficiently impregnated to be boiled down to the crystallizing point, which is done in tinned vessels to about a third of the original quantity. This is then strained, and, on cooling, deposits the acetate in small long needles in irregular whitish crystals. The mother-liquor is again evaporated for a fresh crop of crystals, but these are browner and somewhat deliquescent. Acetate of lead may also be made directly by dissolving ceruse or litharge in vinegar, and probably the natural carbonate will answer the same purpose. Some technical nicety appears to be required in making the salt crystallize in the large way.

Potash.

(610.) This is an article of great application in various branches of the Arts and Manufactures of this Country, and is principally obtained from the combustion of vegetables, although it exists also in a mineral state. If the woody or annual stems of vegetables, which have grown in soils unimpregnated with common salt, after being

Mechanical
Processes.

Sugar of
lead.

Potash.

Manufac-
tures.

sufficiently dried, are set on fire; the watery, resinous, oily, acid, and carbonaceous portions are volatilized and dissipated in a state of more or less complete decomposition, and there remains behind a reddish or whitish powder, called ash or ashes, consisting principally of earthy or metallic ingredients of the vegetable, together with a variable proportion of subcarbonate of potash. By lixiviation with hot or cold water the alkaline part is dissolved out; and this solution, when boiled down to dryness, leaves behind a dark brown saline mass, consisting of the carbonated potash, coloured by a small portion of vegetable, inflammable matter, and in this state it is known in the English market by the name of potash. Calcination, at a moderate red heat, completely burns off the colouring principle, and the salt becomes of a spongy texture, with a fine bluish-white tinge, and is then called pearl ash.

Ash balls
of England
and Ireland.

A large proportion of the potash used in England is imported from foreign Countries which abound largely in woods, as Germany, Russia, and America; but a very rude preparation of the same is produced both in England and Ireland, principally from the burning of heath and fern. In neither, however, can it be considered as a general article of commerce, although considerable quantities are annually made by the peasantry of both Countries, and disposed of amongst the neighbouring farmers and bleachers under the name of *ash balls* or *weed ash*.

In Ireland, the vegetable from which this impure alkali is produced is the common fern or brake. Many rough and heathy districts are entirely covered with this plant, which, when it has attained its growth, about the middle of July, is cut down, and, after being half-dried in the open air, is gathered into smaller heaps and kindled. The combustion proceeds slowly, being accompanied by a smothering smoke and little or no flame, till the whole is reduced to a reddish-grey ash; this being carefully collected is sprinkled with a little water, and then moulded by hand into balls from three to four inches in diameter, which, when they have acquired a certain hardness and solidity by drying in the sun, are ready for sale. In Ireland, thistles, docks, and weeds of all kinds are mixed with the fern, and the ashes are disposed of in their loose pulverulent state, without any further preparation.

The general potash of commerce, or black potash, is, as we have stated, chiefly of foreign manufacture, which can be carried on to advantage only in Countries which are not only thickly covered with wood, but where, for want of roads, or other means, the wood itself cannot be removed to a profitable market, or where the object of clearing the country of wood is of more importance than the wood itself. Different processes are adopted in different Countries, but as the subject is not connected with our present object, *viz.*, an account of the principal Manufactures of Great Britain, it will not be necessary to describe them.

Salt Works.

Common
salt defined.

(611.) Salt, or common salt, is a substance of necessity so immediate to the health and conveniences of life, and of application so extensive in agriculture and in the Arts, that it is perhaps in more general use than any other natural or artificial production whatever. For many years, it was considered by Chemists to be a compound of muriatic acid and soda, the latter having been

supposed a simple body; but Sir H. Davy having succeeded in decomposing soda, common salt is now considered as the chlorate of sodium, the latter being the metallic base of soda.

Mechanical
Processes.

There are three great repositories of salt found in nature; *viz.* sea water, which is impregnated with the elements of this substance; brine pits and brine springs, which are more largely imbued with them; and salt rocks, in which the salt is combined more or less with earthy matter. It is stated above, that common salt is a compound of muriatic acid and soda, or of chlorine and sodium, but this implies its most perfect form; generally, our domestic salt contains, besides the basis of the salt, other foreign matters and impurities, and is indeed distinguished under different heads, according to the sources and processes from which it is derived, or the nature of the foreign matter with which it is combined.

Natural
depositories
of salt.

1. *Bay salt* is a name given to salt prepared by evaporation. This is of two kinds: the first drawn from sea water the second from the water of salt springs or lakes.

Different
sorts of
salt.

2. Marine salt, extracted from sea water by boiling.

3. Brine salt, also prepared by boiling, but from the natural brine of ponds, fountains, or streams.

4. White salt, obtained by first strengthening the sea water or natural brine by evaporation, and then completing the rest of the process artificially.

5. Refined rock salt, boiled from a solution of fossil salt in salt or fresh water.

The climate of this Country will not admit of the formation of salt wholly from natural evaporation; on some parts of our Southern coast it is first concentrated by atmospheric evaporation, and the process completed by artificial heat, but in our Northern Counties, and in Scotland, the whole process is performed by artificial means. The English salt rocks and brine springs are almost entirely confined to Cheshire, of which we shall give a particular description below. At present we shall confine ourselves to the means employed to obtain salt from sea water.

(612.) *Processes for obtaining salt from sea water.*— There are several ways of obtaining salt from sea water; in warm climates, this is done altogether by the heat of the atmosphere; and this forms the large-grained, strong, dry salt, called *bay salt*, which is preferred to any other for curing provisions that are intended to keep for a length of time. Bay salt is made in great perfection in Spain and Portugal, by the Biscayans; on the Mediterranean shores of France, and in the Bahama Islands in the West Indies. The process is simple, and requires but little apparatus of any kind. The first requisite is a sea marsh, or shallow artificial pond, near enough to the sea to be filled at high water; a level shore must therefore be chosen, and the soil must be clayey to retain the water. The bottom of the pond is then laid out perfectly even, and beaten hard and smooth, and a channel with flood-gates is cut to the sea, so that the salt pool may consist of a large reservoir communicating directly with the sea at one end, and at the other with a number of smaller pits or beds on which the salt is made. The water is first evaporated by the sun's heat in the reservoir, and then conveyed to the salt beds, which are only a few inches deep, and in which the evaporation is completed also by the sun and wind, and the salt separated, first in the form of a white crust, which is afterwards broken from time to time to expose a fresh surface to the air. The concentrated brine yields salt about twice, and sometimes

4th method.

thrice a week in the summer. The first saline crust which is formed is small-grained, the latter large. Bay salt has generally a little tinge of colour, green or brown, according to the soil on which it is formed. It is only made in the summer months.

Another way of making salt from sea water, which is practised much on the French and other coasts of temperate climates, is partly by the atmospherical evaporation, and partly by boiling, for the summers are not hot enough in such climates to make salt by mere exposure of brine to the air. The general mode of proceeding is that already mentioned; that is, the sea water is exposed during the summer in shallow artificial pools, where it becomes highly concentrated, and this is afterwards boiled down in iron pans in the usual mode. This way is adopted in some parts of England, particularly at Lymington. The mother-water which remains after most of the salt has been extracted, contains much muriate of magnesia, and this is advantageously converted into the *sulphate of magnesia*.

There is still another method of extracting the salt from sea water, which is by collecting the sand that has been repeatedly moistened by the sea water and dried, and lixiviating it in the reservoirs, where it forms a very strong brine, which is then boiled down as usual. This method is much practised on the Western coast of France, particularly in Lower Normandy, and at the Isles of Oleron and Rhé.

The spot being chosen, (which should be on a level shore with a clean sand,) the necessary buildings are erected, namely, evaporating pans, store-houses, covered sheds, &c., and an area of three or four acres is selected a little below the level of the spring tides and above the neap. The surface is carefully levelled by the plough, and rolled smooth and hard; it is then filled to the height of several inches with sand taken from the edge of the sea at low water, and the sand is also drenched with sea water as the tide flows in. It then lies exposed to the sun and wind, which soon dissipate the superfluous water, and the surface of the sand appears covered with a white efflorescence. This is turned over frequently with a kind of shovel, changing the surface several times a day till the whole is thoroughly dry. This saline sand is then carried to the sheds, and the process is repeated with fresh sand till a large quantity is collected, which generally employs the whole summer. To make the salt, the dry sand is taken out of the sheds and thrown into small round pits about two and a half feet in diameter, and twelve inches deep, the bottoms of which are lined with hard-rammed clay mixed with chopped straw, to prevent the water from oozing through. The sand is then covered with sea water, or with the weaker lie of former operations, and after standing some hours is drawn off into reservoirs or barrels, whence the evaporating pans are immediately supplied. The sand is lixiviated a second time, and this lie is reserved for a fresh portion of sand. The boilers are of lead, about three and a half feet square, and four or six inches deep. They are heated with wood of any kind, or sometimes with reeds, and a boiler of this kind is worked off in from two to three hours. The salt is raked out as it is formed, and drained in hollow cones, as in other places. Three pans of the above dimension yield together about five pounds of salt.

The salt procured in this way is white and small-grained, but it is very apt to be damp, and is a weak-bodied salt little fit for preserving animal food for any length of time. In a few Northern Countries, some

advantages is made of the effect of cold to concentrate brine, by freezing at first only the more watery part, of course leaving the unfrozen part proportionally richer in salt. The winters of this Country are not cold enough in general for this purpose, but it is occasionally used on the Baltic coasts. The cold, however, must not be too intense, otherwise the brine itself freezes. Frozen salt water is not in hard solid masses like fresh water, but is soft and crumbly or rotten. The efficacy of this method of concentrating brine is very inconsiderable.

(613.) *Description of the Cheshire salt district.*—We have stated the other repositories of salt to be salt rocks and brine springs, which in England are found only in Cheshire and its immediate neighbourhood. A very interesting account of this salt district has been given by Mr. Holland, in a Memoir published in vol. i. of the first series of the *Transactions of the Geological Society*, from which it appears that the rock salt occurs from 28 to 48 yards beneath the surface of the earth. The first stratum or mine is from 15 to 21 yards in thickness. It very much resembles in appearance brown sugar-candy, is perfectly solid, and so hard as not to be broken but with great difficulty by iron pikes or wedges. Of late, the workmen have been accustomed to blast it with gunpowder, by which means they loosen and remove many tons of it together. Beneath this stratum there is a bed of hard stone, consisting of large veins of flag, intermixed with some rock salt, the whole from 25 to 35 yards in thickness. Under this bed is a second stratum or mine of salt, from five to six yards thick, many parts of it perfectly white and clear as crystal, others browner, but all purer than the upper stratum, yet reckoned not quite so strong. Only these two distinct beds of the fossil salt have been met with at Northwich; but it has been ascertained that the same limitations do not exist throughout the whole of the salt district, three distinct beds, at least, being found in some situations, separated in like manner from each other by intervening strata. The great body of the rock salt, both in the upper and the lower beds, is composed of crystals of muriate of soda, intimately mixed with certain proportions of clay and oxide of iron, containing likewise small proportions of certain earthy salts. At the same time, particularly in the lower strata of the rock, there are found separate crystalline concretions of muriate of soda in a purer state, variously disposed, sometimes occurring distinctly in the cubical form, in other places in masses of larger size and irregularly shaped. Above the whole mass of salt lies a bed of whitish clay, which has been used in the Liverpool earthenware; and in the same situation there is found also a quantity of gypsum.

(614.) Rock salt-pits are sunk at great expense, and are very uncertain in their duration, being frequently destroyed by the brine springs bursting into them, and dissolving the pillars that support the roof; through which the whole work then falls in, leaving vast chasins in the surface of the earth. In forming a pit, a shaft or eye is sunk, similar to that of a coal-pit, but more extensive. When the workmen have penetrated to the salt rock, and made a proper cavity, they leave a sufficient substance of the rock (generally about seven yards in thickness) to form a solid roof; and as they proceed, they hew pillars out of the rock, to sustain the roof. Gunpowder is then employed to separate what is meant to be raised, which is conveyed to the surface in huge craggy lumps, and is drawn up above ground in capa-

cious baskets made for the purpose. When well illuminated, the crystalline surface of the roof, pillars, and sides of a large pit make a glittering and magnificent appearance, which seldom fails to have a very impressive effect on the mind of a stranger. Fresh air is conveyed from the mouth of the pit by means of a tube with a pair of forge bellows fixed to it; and thus a perpetual current is preserved between the outer and inner air. The pits, at the greatest depth, are dry, and of an agreeable temperature.

The largest rock salt-pit in Cheshire is one in the town of Wilton. This has been excavated in a circular form to 108 yards in diameter; its roof is supported by 25 pillars, each three yards wide at the front, four at the back, and six yards in the sides. Each of these pillars contain 294 yards of rock salt, and the whole area of the pit, which is 14 yards hollow, includes 9160 superficial yards, or little less than two acres of land.

The quantity of rock salt delivered annually from the pits in the neighbourhood of Northwich, is from 50,000 to 60,000 tons. Hardly more than one-fourth of this is refined in England, the remainder being exported to various parts of the Continent. The salt is conveyed down the Mersey in vessels of from 50 to 80 tons burthen to Liverpool, where it is reshipped for foreign Countries, or kept to be refined.

Besides the great quantity of salt obtained from the rock, an immense weight is supplied by the brine pits, not less than 45,000 tons being annually manufactured at this town, or in the vicinity. The usual depth of the springs is from 20 to 40 yards; and they are situated on a hill at some distance. The brine stream is raised by a steam engine, and conveyed through very long troughs to the brine pits. The process of extracting the salt is accomplished by heating the liquor in iron pans of from 20 or 30 feet square, and about 14 inches deep. When it boils, a light scum rises to the top, which is taken off, and the liquor reduced to a lower degree of heat; the stream arising is made to evaporate as quickly as possible; and the salt collecting into crystals forms a crust on the surface, which, sinking afterwards to the bottom of the pans, is thence removed once or twice in every twenty-four hours. The salt made in this district is distinguished into stoved or lump salt, common salt, large-grained flaky salt, and fishery salt.

(615.) *Lump or stoved salt.*—In making this salt, the brine is brought to the boiling heat, which in brine fully saturated is 226° Fahrenheit. This temperature is continued during the whole process; and as the evaporation proceeds, small flaky crystals continue to form themselves, and to fall to the bottom of the boiler. At the end of from eight to twelve hours, the greatest part of the water of solution is found to be evaporated; so much only being left as barely to cover the salt and the bottom of the pan. The salt is then removed into conical wicker baskets termed *barrows*, and, after being well drained, is dried in stoves, where it sustains a loss of about one-seventh of its weight.

On the first application of heat to the brine, a quantity of carbonate of lime, and sometimes a little oxide of iron, both of which had been held in solution by an excess of carbonic acid, are separated, and are either removed by skimming, or are allowed to subside to the bottom of the pan along with the salt first formed and with some sulphate of lime, and are afterwards raked out. These two operations are called *clearing* the pan. Some brines scarcely require them at all, and others

only occasionally. The whole of the impurities, however, are not thus removed; for a part subsiding to the bottom, forms a solid incrustation, termed by the workmen *pan-scale*. The portion of this which is lowest acquires so much induration and adhesion to the pan, that it is necessary to remove it once every three or four weeks by heavy blows with a pick-axe. These sediments are formed also in making the other varieties of salt.

Common salt.—The brine for forming this salt is raised to a boiling heat, with the double view of bringing it as quickly as possible to the point of saturation, and of clearing it from its earthy contents. The fires are then slackened, and the evaporation is carried on for twenty-four hours with the brine heated to 160° or 170° Fahrenheit. The salt thus formed is in quadrangular pyramids or *hoppers*, which are close and hard in their texture. The remainder of the process is similar to that of making stoved salt, except that, after being drained, it is carried immediately to the store-house, and not afterwards exposed to heat, an operation confined to the stoved salt.

Large-grained flaky salt is made with an evaporation conducted at the heat of 130 or 140 degrees. The salt thus formed is somewhat harder than common salt, and approaches more nearly to the cubic shape of the crystals of muriate of soda.

Large-grained or fishery salt is prepared from brine heated only to 100° or 110° Fahrenheit. No perceptible agitation, therefore, is produced in the brine, and the slowness of the process, which lasts from seven or eight to ten days, allows the muriate of soda to form in large and nearly cubical crystals.

For ordinary domestic uses, stoved salt is perfectly sufficient. Common salt is adapted to the *striking* and salting of provisions, which are not intended for sea voyages or warm climates. For the latter purposes, the large-grained or fishery salt is peculiarly fitted.

All the pans were formerly, and are still in many works, heated by furnaces beneath them with flues drawing all round, and the fuel is commonly coal; but recently the evaporation is produced by means of steam, as described below. In the former case, each of the pans, which are set securely upon masonry with the furnace below, stands in a covered building, with a pyramidal roof formed of boards sloping downwards, but with a considerable interval between each to keep off the rain, but allowing, at the same time, a free passage for the steam of the boiling brine to pass off.

(616.) *Evaporating by steam.*—Two patents have been granted for evaporating by means of steam, instead of the usual furnace and flues, in one of which a vessel containing the brine is inserted in a steam boiler, or intimately connected with it, the brine vessel being open on its upper part.

In the second by Mr. Furnival, the brine is, as in the other, first pumped into an open vessel at A, fig. 5, plate xlvi., inserted in or fixed upon a close steam boiler B; but the boiler, instead of containing fresh water, contains a still stronger brine than that in the upper vessel. This is brine which has been operated upon in the upper boiler, and let down into the lower one to be finished or evaporated to such a degree that nothing but salt remains. To effect this, a division of sheet iron C is made in the top or upper side of the lower boiler in a diagonal direction, containing an opening d, similar to a dormer window in a leaning roof. This

serves to let out the steam, but will not admit any condensed water to enter. The steam raised in the lower boiler rushes through this opening in the iron partition, and acts upon the upper boiler so as to heat it and evaporate it to a certain degree, and this steam being condensed falls down upon the cover of the sloping cover of the lower boiler, and runs off through the waste pipes *e* to the drain, as shown in the figure.

The waste water being warm, imparts heat to the brine as it is conducted along the pipe *p*, which is the pipe of a force-pump for forcing the raw brine from the brine well to the upper boiler, and which is laid along the waste drain *f* for this purpose: *nn* are rakes with iron handles working through air-tight stuffing-boxes *b*; these are for the purpose of raking the salt to the fore part of the boiler where it is taken out at the man hole *m*.

The lower boiler must be provided with a safety

valve in the usual way. Alderson on the Steam Engine

Mechanical Processes.

The following Table shows the result of a course of experiments to determine the amount of impurities in different descriptions of salt, by Dr. Henry, and published by him in the *Philosophical Transactions* for 1810. These experiments were undertaken principally with a view of ascertaining the comparative qualities of different foreign and British salts.

Dr. Henry's analysis.

From an examination of the results in the last two columns, the total amount of impurities, and the quantity of muriate of soda contained in each variety of common salt, may be immediately seen; and from these it appears that the foreign bay salt is purer, generally speaking, than salt which is prepared by the rapid evaporation of sea water, but that it is contaminated more than twice as much as the *stoved* and *common* salt of the Cheshire district.

Epsom salts.

(619.) *Epsom Salts*, or sulphate of magnesia, would hardly have been thought of sufficient general interest as a British product to be introduced in this place; but it is so intimately connected with the preceding article, that a few lines descriptive of the process of its manufacture will not, we trust, be considered misplaced. In order to illustrate this, it will be necessary to describe a little more particularly than we have done, the process followed at Lymington, in Hampshire, in the formation of common salt. As the climate there is warmer than in most other parts of our coast, advantage is taken of this circumstance to concentrate the sea water by spontaneous evaporation to about one-sixth of its bulk, before admitting it into the boilers; and one difference in the subsequent process is, that the salt is not there *fished* out of the boilers and drained, as we have before

described, but the water is entirely evaporated, as by the patent apparatus, and taken out once every eight hours and removed into troughs having holes in their bottoms. Through these it drains into pits made under ground, which receive the liquor called *bittern* or *bitter liquor*. Under the troughs, and in a line with the holes, are fixed upright stakes, on which a portion of salt, that would otherwise have escaped, crystallizes, and forms, in the course of ten or twelve days, on each stake, a mass of sixty or eighty pounds. These lumps are called *salt cats*. They bear the proportion to the common salt made from the same brine of one ton to one hundred.

From the mother-brine or bitter liquor, which has drained into pits, the sulphate of magnesia is made during the winter season, when the manufacture of salt is suspended, in consequent of the want of the temperature required for the spontaneous evaporation of the sea water. The process is a very simple one. The bitter liquor from the pits is boiled for some hours in the pans which are used in summer to prepare common salt, and the impurities, which rise to the surface, are removed by skimming. During the evaporation, a portion of common salt separates; and this, as it is too impure for use, is reserved for the purpose of concentrating the brine in summer. The evaporated bitter liquor is then removed into wooden coolers, eight feet long, five feet wide, and one foot deep. In these it remains twenty-four hours, during which time, if the

Manufac-
tures.

weather proves clear and cold, the sulphate of magnesia, or Epsom salt, crystallizes at the bottom of the coolers, in quantity equal to about one-eighth of the boiled liquor. The uncrystallizable fluid is then let off through plug-holes at the bottom of the coolers, and the Epsom salt, after being drained in baskets, is deposited in the store-house. This is termed *single* Epsom salts, and after solution and a second crystallization, it acquires the name of *double* Epsom salts. Four or five tons of sulphate of magnesia are produced from a quantity of brine which has yielded one hundred tons of common and one ton of cat salt.—*Philosophical Transactions*, 1810.

Saltpetre Works.

Saltpetre,

(620.) Although, in consequence of the facility with which England is supplied with this important element of war from her possessions in the East Indies, and her trade with China, we have no saltpetre works in this Country, yet it would perhaps be considered an improper omission if we did not devote a few lines to an explanation of the depositories of the components of this salt, and the processes followed in its manufacture. Saltpetre may be esteemed both as a natural and artificial product, although in its former character we must consider it as a recent formation. It occurs in two different repositories, *viz.* in limestone and in vegetable soil. The calcareous repository is a peculiar variety of secondary flætz limestone, or calcareous tufa or chalk, or indurated marl. In these rocks it occurs in a thin, granular crust, or in an efflorescence of minute specular crystals, overspreading the outside, and particularly lining the insides of caverns both natural and artificial; and, hence, probably, is derived its ancient name saltpetre, or salt rock. Calcareous strata containing nitre are found in many parts of the globe, but the most celebrated repository of native nitre is the Pulo of Molfetta, in the Kingdom of Naples. The Pulo is a deep cavity in the form of an inverted cone, produced by the falling in of several natural caverns, and communicating with other lateral caverns, both natural and artificial. The whole of these caves, when attention was first called to them by the Abbé Fortis, were covered with an efflorescent crust of saltpetre more than an inch in thickness, which after being scraped off was again renewed in the course of a few days in constant succession. Similar formations, on a less scale, are obtained in many other places. The other source from which nitre is derived is vegetable soils. In Spain, Hungary, in some parts of France, and various other Countries, very rich productions of nitre are obtained from the natural soil; in others, ground is artificially prepared for the purpose; the surface is swept or gathered at intervals and lixiviated, the liquor is then boiled down, and affords, by cooling, a quantity of nitre mixed with common salt, varying of course according to circumstances.

obtained
from
caverns,

and from
vegetable
soil.

Processes
employed in
lixiviation.

The process of lixiviation is performed in the following manner. Several cart-loads of nitrous earth are mixed as accurately as possible with the requisite quantity of alkali, either in the form of wood ashes or pulverized potash; the proper quantity or proportion being first determined by experiment on a small weight of the earth.

Several large casks, with perforated false bottoms, are now filled with the prepared earth, laid on very lightly, after which as much river water is poured in as the

vessels will hold. In two or three hours' time the cock at the bottom of each cask is turned, and the liquor is allowed to drain out during the remainder of the day. The casks of a second series, charged with earth as before, are now filled up with the first lixivium, and after standing for a few hours the liquor thus concentrated is drawn off in the manner just described. By a similar process on the third day, a lixivium thrice as strong as the first is obtained, which is now sufficiently concentrated to be boiled down. The contents of each series of casks are lixiviated twice more, and the weak solutions thus obtained are employed instead of water in the first and second lixiviations of fresh parcels of earth.

Mechanical
Processes.

The boiling down and evaporation next succeeds. Boiling and The lixivium, containing nitrate of potash, the muriates of evaporating potash and soda, with probably a few other salts, and various earthy and other impurities, is put into a large boiler like a salt-pan, and heated nearly to ebullition; it is then clarified by the addition of bullock's blood or solution of glue, the impurities as they appear on the surface being carefully skimmed off. When no more froth rises of itself, a little lime-water is added, which coagulates the remainder of the blood and glue, and thus completes the clarification. It is now boiled for several hours, and the muriates of potash and soda, as they are deposited, are withdrawn by a perforated ladle. When the liquor is so concentrated that a few drops crystallize readily on being dropped on a cold iron, it is laded out into a vat, where it remains a short time to deposit the common salt and impurities still floating in it: thence it is transferred to a large wooden or metallic crystallizing basin, in which it remains closely covered up during from three to six days, according to the temperature of the air; at the expiration of which period the fluid mother-water is poured out and returned to the nitre bed, and the salt, deposited in a confused, crystalline mass of opaque, dirty white, is broken to pieces and set to drain, after which it is brought to market, or delivered in to the Government stores as rough nitre, or nitre of the first boiling.

In order to refine the rough nitre, the old practice Refining was to subject it to two more successive boilings and process. crystallizations; by this method, however, a very considerable proportion of the nitre was left in the mother-waters; no inconsiderable share was volatilized by the heat required for evaporating the solution when it had nearly acquired the due degree of concentration; and, besides, a great expense of both time and fuel was incurred. The modern method of refining this salt was invented in France a few years ago, and is now considered as brought nearly to perfection. It is thus effected:

The rough nitre is broken to small fragments by wooden mallets, and is then put into a wooden tub with 20 per cent. by weight of cold water; in this state it remains for six or seven hours, being occasionally well stirred up that the water may have free access to every part. The water is now let out by a hole at the bottom of the vessel, and carries with it in the solution all the deliquescent salts, and the greatest part of the muriates of soda and potash, together with some nitre. When the whole of the liquor is drained off, 10 per cent. more of water is added and well mixed with the nitre for an hour's time, when it is discharged in the same manner as the first. Lastly, 5 per cent. of water is poured in and run off again almost immediately after. The nitre thus washed, after being well drained,

Manufac-
tures.

is put into a boiler with half its weight of water, and boiled till a pellicle forms on its surface; the liquor is then discharged into a large leaden cooler, and stirred about with rakes till it is quite cold, by which manipulation the salt is deposited in small crystalline needles. It is now taken out of the liquor with a perforated ladle and well drained; after which it is washed with 5 per cent. of cold water and again drained: being then spread out on a large table, it dries in a few hours, and is, lastly, heated over a fire in large basins for two or three hours, at a temperature not exceeding 120° Fahrenheit, taking care to stir it all the while. By this treatment it is perfectly purified and brought to the consistence of fine sand, and is now ready to be manufactured into gunpowder. Aikin's Dictionary.

Soap Works.

(622.) Common soap is composed of any kind of oil, either vegetable or animal, with fixed alkali, either potash or soda. Besides these substances, lime is essential to give the alkali the requisite degree of causticity; and in those soaps in which the alkali employed is potash, the addition of common salt is also required. Soap is manufactured in this Country principally from tallow, or any other fat, and the alkali made use of is either barilla or pearl-ash, or a mixture of the two, according to the price and practice of the manufacturer. But as potash alone will not make a stiff soap, recourse is had to the action of common salt, which, when added after the potash and oil are united, produces a separation of the compound from the water incorporated with it, hardens and renders it equal to the soda soaps.

Process for
making
white soap
with pot-
ash.

The following is the usual method of making the common white and yellow soap used in domestic purposes.

White hard soap is generally made with three separate charges of lie. The potash (when this alkali is used) is previously dissolved with water in a small boiler with a little fire, and the solution is poured over a vat containing common wood-ashes mixed with lime,

which gives the first and strongest lie. As soon as this has run off, the ashes are turned, more lime is added, and water is pumped on, which forms the second or weak lie. The large boiler is then charged with the tallow, and about two-thirds of the strong lie being added, a moderate fire is kept up to incorporate the materials, which is known by their running into a stiff glue. If this does not take place in about seven hours, (with twenty-nine hundred weight of tallow in the boiler,) more alkali must be added. The tallow is then termed *killed* or saturated; the fire is drawn, and the materials are allowed to remain at rest for a short time.

Common salt is now thrown in, and stirred up with long poles till it is thoroughly incorporated, and till the matter changes from a dark-coloured glue to a thin soapy substance. A brisk fire is then made, and the materials are boiled for a few minutes, when the fire is again drawn and the materials in the boiler are allowed to settle for an hour and a half, during which the spent lies sink to the bottom of the boiler and are pumped off. The second operation begins by raising the fire and adding to the soapy mass the weak lie, which is to be managed in the same manner as the first; this again brings it to the state of a glue, which a very little salt will restore to the saponaceous state, and after boiling and cooling, the second lies are pumped off.

In the third operation, the third part of the strong lie which was reserved is added, which, as before, changes the mass to a thick glue, and must be again grained with salt. The contents are then boiled strongly for three hours, more or less, till by taking samples occasionally with a trowel, the soap is felt sufficiently hard and dry to the touch, and the lie will be seen to run off quite clear from the soap on the trowel, leaving the latter in sound lumps.

The boil of soap is then finished by pumping off the spent lie and scraping off a quantity of light froth from the top of the soap. The soap is then fit for *framing*, which is a perfectly simple process. The frames are wooden troughs, with a movable bottom, into which the soap is poured while still fluid, and allowed to remain for three or four days till it is stiff enough to be handled without sinking in. The soap is then taken out and cut into long prisms with a brass wire, and kept for some time in an airy room till it has become of the requisite hardness, and is then fit for sale.

In making yellow soap, a quantity of rosin is added to the oil and tallow. The lie is prepared in a similar vat, and the arrangement of the processes is in other respects the same as in forming white soap.

With regard to the proportions of ingredients, it is reckoned that sixteen bushels of good wood-ashes are equal in alkali to one hundred weight of the best pearl-ash, and that this latter quantity will saturate two hundred weight of tallow, and produce three hundred weight one quarter of soap; so that twelve parts of tallow will make twenty of soap: also twelve bushels of wood-ashes are equal to one hundred weight of barilla; and the latter quantity will saturate one and a half hundred weight of tallow. A boil of twenty-nine hundred weight of tallow with ten hundred weight of barilla and five hundred weight of pearl-ash requires about eight hundred weight of common salt. The common salt seems to have another use in soap making, in addition to the one we have already described, *viz.* that of promoting the grain-ing or separation of the soap from the spent lie, which it does prooably by simply extracting the watery part.

Mechanical
Processes.

Manufactures.

In this way it is as much used in the soda as in the potash soaps; and in each it considerably hastens the process, but it is by no means essential, as it appears to be seldom used where barilla or soda is the sole alkali.

Process for making soap made with kelp and tallow.

Hard soap is made in Scotland chiefly with kelp and tallow. That crude alkali rarely contains more than from one to five per cent. of free soda, mixed with some sulphate and hydrosulphate, and nearly 33 per cent. of muriate of soda.

To every ton of kelp broken into small fragments, about one-sixth of new-slacked lime is added. The whole after mixture is put into a large tub called a *cave*, having a perforation at the bottom shut with a wooden plug. Upon the materials, water is very slowly poured, and the liquor, after digestion, is suffered to run slowly off into a reservoir sunk in the ground. The first portion, or lie No. 1, is of course the strongest, and is reserved for the last operation of soap-boiling. A gallon of this lie, of the average strength, contains 1000 grains of real soda, so that one pound of alkali is present in seven gallons of lie. The second portion run off contains 800 grains in one gallon, equivalent to a pound in 8 $\frac{1}{4}$ gallons. The third contains 600 grains per gallon, or one pound in 11 $\frac{1}{2}$ gallons, and the fourth 200 grains, or one pound in 35 gallons. The last is not employed directly, but is thrown on a fresh mixture in the cave to acquire more alkaline strength.

Six days are required to make one boiling of soap in which two tons or upwards of tallow may be employed. The lies 2 and 3 mixed are used in the beginning diluted with water on account of the excess of sea salt in the kelp. A quantity of lie is poured on the melted tallow and the mixture is boiled, while a workman agitates the materials to facilitate the combination. The fire being withdrawn, and the aqueous liquid having subsided, it is pumped off and a new portion is thrown in. A second boiling is given, and so on in succession. Two or three boilings are performed every six days, constituting twelve or eighteen operations in the whole. Towards the last, the stronger lies are made use of, but as soon as the workman perceives the separation perfect, the process is stopped and the soap is lifted out and put into moulds to dry.

Another process for white soap.

The following is the process given by Macquer for making hard white soap from tallow and soda.

A lie is prepared with two parts of good Spanish soda, and one of quicklime, boiled in a vessel with twelve times as much water, which must be filtered and evaporated until an ounce phial will contain one and three-eighths of an ounce of this concentrated lie. Mix with 200 gallons of lie ten hundred weight of the best tallow, which must be melted over a moderate fire and at the end of two hours drawn away, and the pan allowed to settle for about the same length of time, when the lie may be drawn off. Two or three boilings may be given every day, which must be continued day after day until the whole assume the appearance of a curdy mass. A portion is then examined by squeezing it between the finger and thumb, and if it has the appearance of thin hard scales it is fit for finishing. If, on the contrary, it is of a soft consistency, appearing greasy, and sticks to the finger, more lie must be added, and if that does not sufficiently harden it, another boiling must be given.

When the soap is found to assume the light appearance of hard scales, it must have another boiling, and after being cooled down by two or three pails of lie, must remain two hours, and the lie be again pumped

from it. The next operation is that of boiling it with about 80 or 90 gallons of water, the whole being well incorporated together by stirring; 10 gallons of a solution of salt, of one part of salt in three of water, are then added, which has the effect of separating the soap from the water. The fire is then withdrawn, and after the whole has stood for half an hour, the water is pumped off, which will carry with it the remainder of the alkaline lie of the former boiling.

This operation is termed the *first washing*; a second must be given by 60 or 70 gallons of water more; and in some cases a third, according to the degree of consistency required in the soap. The soap must then be left to stand for twelve or fourteen hours, when it will be ready for the operation of framing already described, which completes the manufacture. Fine white soap is made with one part of the above lie with two of oil of olives, or oil of sweet almonds, which must be stirred occasionally with an iron spatula till it is thick and white. The ingredients gradually combine, and in seven or eight days a firm and very white soap is obtained.

(623.) *Soft soap*.—This is a compound of fats or oils with potash alone, and does not in consequence acquire the consistence of hard soap. There are three kinds known in commerce: soap from oleaginous seeds, called *green soaps*; from hog's lard, termed *toilette soaps*; and others from rapeseed.

Manufacturers of green soap prepare their potash lies as those of hard soap do their soda lies, and conduct their operations in the same way till the oils are added. In this state the soap resembles an unguent; it contains an excess of oil, is white, and nearly transparent. After tempering the fire, they keep continually stirring the bottom of the caldron with large spatulas, and add by degrees new lies, perfectly caustic and somewhat stronger than the first, by which the saturation of the oil is effected and the soap becomes transparent. The fire is continued until the soap is of a suitable consistency, after which it is run into barrels for sale.

The following particulars on the manufacture of soft soap are given in Dr. Ure's *Dictionary*, for which he states himself to be indebted to an eminent manufacturer at Glasgow.

273 Gallons of whale oil and 4 hundred weight of tallow are put into a boiler with 252 gallons of potash lie, whose alkaline strength is such that one gallon contains 6600 grains of real potash. Heat is applied when the mixture froths up very much, but is prevented from boiling over by a wooden crib which surmounts the iron caldron. If it now subside into a doughy magma, it shows that the lie has been too much concentrated, its right appearance being a thin, gluey mass. There is next poured in two measures of a stronger lie holding each 21 gallons, (containing per gallon 8700 grains of real potash,) and after a little interval, another two measures, and so on progressively until 14 measures have been added in the whole. After suitable boiling without agitation, the soap is formed, amounting in all to 100 firkins of 64 pounds each, from the above quantity of materials. Rape oil forms a hard soap, neither so consistent nor so white as that of olive oil. Hempseed produces a green-coloured soap, which may be reduced to a paste by a small portion of water. The soaps prepared with oils produced from the beech-mast and clove July flowers are of a clammy glutinous consistence, and generally of a greyish colour. Nut oil forms a soap not proper for the hands; it is of yellowish-white colour and of a moderate degree of consistence, unctuous

Mechanical Processes.

Manufac-
tures.

gluey, which it continues to be after exposure to the air. The soap of which linseed oil forms a constituent part, is at first white, but changes to yellow in a short time by exposure to the air: it possesses a strong odour, is unctuous, clammy glutinous, does not dry in the air, and softens with a very small quantity of water.

From what has been said, we may conclude that the soaps prepared with desiccative oils are of a very indifferent quality, that they remain always glutinous and readily change their colour on exposure to the atmosphere.

(624.) The following are the quantities of hard and soft soap charged with duties of Excise in the United Kingdom, and the net produce of the duty in each year, from 1820 to 1831.

Sulphur Works.

Sulphur

(625.) Sulphur occurs native in many places, particularly in the Kingdom of Naples, and is frequently nearly in a state of purity, or slightly combined with earths. The whole preparation which it requires, therefore, in this case, to render it fit for the purposes of commerce, is to free it from its earths by distillation.

In other cases it is obtained artificially in the roasting of copper ore, as at the celebrated Paris mountain copper mine in the Island of Anglesea. There works for that purpose are constructed on a large scale. At the foot of a low but a steep ridge of rock are constructed masses of masonry, not unlike high blast-furnaces, except that the top is capped with a dome of brickwork, from which proceeds a horizontal flue, about the size of a common chimney, which terminates in a square or oblong brick chamber, built at the top of the rock. Some lighted fuel is introduced by means of a door in the dome of this roasting furnace, and a few baskets full of ore, broken into moderately small pieces, are thrown on, fresh parcels of ore being added from time to time; as the preceding parcels get lighter, a sufficiency of air for the slow combustion required in this process is let in by means of a door at the bottom of the kiln, which also serves for taking out the ore when properly roasted; the part of the sulphur which escapes combustion rises in vapour, and collects in the dome, (the door of which is only opened to admit fresh charges of ore,) whence it passes through the flue into the chamber, where it presently concretes, lining the sides and roof; each chamber has a door, by means of which, about once in six weeks, it is cleared of the sulphur. This rough sulphur is in spongy, pulverulent crusts, of a dirty greyish-yellow colour. For its purification it is melted in a boiler, the impurities are got rid of by skimming and subsidence, and the fluid mass is then laded into cylindrical moulds to form the common roll sulphur or brimstone, or into cones about two feet high, forming the loaves of sulphur. The impure dregs are also sold in the shops under the name of *sulphur vivum*. The sulphur which is procured in the roasting of ores, especially those of copper, is apt to contain, besides earthy impurities, a very considerable proportion of arsenic, while, on the other hand, the volcanic sulphur in general, and that of Sicily in particular, is entirely free from this contamination; which is the cause of the universal preference given by the manufacturers of sulphuric acid to Sicilian over English sulphur.

Manufac-
tures.*Vitriol Works.*Manufac-
ture of sul-
phuric acid.Process
described
by Dr.
Aikin.

(627.) *Sulphuric acid or oil of vitriol.*—Sulphuric acid is largely employed in various branches of the Arts and Manufactures. It was formerly wholly obtained by distillation from sulphate of iron, and this practice is still followed in some parts of the Continent; but the process generally adopted in this Country is by the combustion of sulphur and nitre, and is described by Dr. Aikin to consist of, first, having a chamber constructed of framework and lined with strong sheet lead, the only opening being a small door, made to shut very close, the bottom of which is a little higher than the floor of the chamber. Water is poured into this chamber till it rises to the height of an inch or two from the floor, and a stand is introduced, in which is placed an earthen pot, containing a few pounds of sulphur and of nitre, in the proportion of from eight to ten of the former to one of the latter; this mixture is set on fire by means of red-hot iron, and the door immediately closed; at the end of about six hours another charge of sulphur and nitre is introduced, which, after a similar interval, is replaced by a third, and so on, without intermission, for a fortnight or three weeks. At the end of this time, the water in the chamber is sufficiently acidulated, and is then transferred to a leaden boiler, where the greater part of the water is evaporated; in proportion, however, as the acid becomes more concentrated, it has the more tendency to corrode and dissolve the lead of the boiler; therefore, before it arrives at this state it is transferred into large, green glass retorts, where a degree of heat is supplied sufficient to drive off almost the whole of the water. As the acid becomes stronger it also becomes clearer and less coloured, in consequence of a portion of the acid reacting upon the impurities with which it is tinged and thus destroying them.

When the acid is thus brought to the required density and clearness, it is poured out of the retorts into large globular, glass bottles, surrounded with wickerwork and lined with straw, called *carboys*. In this state it is brought into the market.

By Dr. Ure.

Dr. Ure's description differs a little from the above and is somewhat more minute. The ordinary form of the sulphuric and lead chamber he states to be a parallelopiped, about seventy feet long, ten or twelve high, and fifteen wide. At the middle height of one end, a small oven is built up with a cast iron sole, having a large lead pipe, ten or twelve inches diameter, proceeding from its arched top into the end of the lead chamber. On the sole the sulphur is burned, the combustion being aided, when necessary, by heat applied from a little furnace below it. Above the flaming sulphur a cast iron basin is supported in an iron frame, into which the nitre, equal to one-tenth of the sulphur, is put, with a little sulphuric acid. The combustion of the sulphur is regulated by a sliding door in the oven. In the roof of the remote end of the large chamber a small orifice is left for the escape of the atmospherical azote and other incondensable gases. This apparatus is used for the continuous process. But there is another, or that of the *intermitting* combustion, which is worthy of notice. Long flat trays, containing the sulphur and nitre, are introduced into the interior of the chamber, or into the oven, and fire is applied to the materials. When the sulphur is burned, and the chamber is replete with sulphurous and nitrous acids, a stream of water is thrown in, in determinate quantity, by a small pipe at the side. This causes a tumultuous

VOL. VII.

motion among the gases and the atmospheric oxygen, which favours the mutual reaction. As the steam condenses, the sulphuric acid falls with it. After some time, the chamber is aired by opening valves of communication with the external atmosphere. The operation is then commenced anew.

Instead of using nitre, nitrous gas, disengaged from nitric acid by sugar or saw-dust, is introduced into the chamber containing the fumes of burning sulphur, whereby the chemical reaction above described is produced, and then steam is thrown in to complete the process and condense the sulphuric acid. The bottom of the lead chamber should never be covered with pure water, but even in the first operation with a dilute acid, introduced on purpose. When nitrous acid comes into contact with water and an excess of atmospheric oxygen, it is converted into nitric acid and nitrous gas. This aeriform body gets more oxygen and changes to nitrous acid, and thereafter to nitric. Hence a chamber with its bottom covered with water will, in some cases, fail in producing any sulphuric acid at all. Water moderately charged with sulphuric and sulphurous acids prevents the transition of nitrous into nitric acid, and allows the process of acidification of the sulphur to go on freely.

Ure's Dictionary.

(628.) *Sulphate of zinc or white vitriol.*—The impure sulphate of zinc, called in commerce white vitriol, is of a bluish-white colour, with ochrey stains externally: it has a granular crystalline texture like loaf sugar, and is in irregular, lumps or masses. The English white vitriol is prepared for the most part by direct solution of a metallic zinc in sulphuric acid, and is therefore purer than the foreign, though it still contains a quantity of iron. Both kinds may be considerably, though not entirely, purified by solution in water, and then abandoning the liquor to spontaneous evaporation in an open vessel containing some granulated zinc, the sulphate of lead will subside to the bottom, and other foreign sulphates will be decomposed by the metallic zinc. The saline mass, when dry, is to be lixiviated with cold water, and the clear filtered solution, after due evaporation, will afford regular crystals of sulphated zinc.

Manufac-
ture of
white
vitriol.

(629.) *Sulphate of copper or blue vitriol.*—This is not manufactured at large in sufficient quantity to give the process a place in this general list of what we have called Works. If copper filings or clippings of thin sheet copper be put into a glass vessel with about twice their weight of sulphuric acid, and the mixture be heated, solution will take place. When this begins, much sulphuric acid gas is given out, (and this is a very convenient way of procuring this gas,) and at last the whole is dissolved into a dark-coloured liquor, except a small quantity of black residue, which is the sulphuret contained more or less in all common copper, and by dilution in water the liquor becomes a fine blue. This solution, by due evaporation and cooling, furnishes crystals also of the same colour, and, when regular, which, however, they seldom are, they assume a rhomboidal shape, which is the blue or Roman vitriol of commerce.

Blue vitriol.

(630.) *Sulphate of iron or green vitriol.*—This salt is of extensive use in the Art of dyeing and other processes. It is not commonly formed by a direct combination of its natural ingredients, but is obtained from various kinds of native sulphates of iron or pyrites.

Manufac-
ture of
green vitriol.

The first English work of this kind was established at Deptford, where it is still carried on; and several large

Manufac-
tures.

works are also employed in the same manufacture in Durham and Northumberland. The process of forming this salt in 1678 is described by D. Colwell, Esq., in vol. xii. of the *Philosophical Transactions*, and it is extraordinary to find amongst the numerous changes which the Arts and the Manufactures of England have undergone in this series of years, how little difference there is in this one in particular. It is unnecessary to transcribe Mr. Colwell's account, but by referring to it the reader will find how little it differs from the following, communicated to Dr. Aikin, as descriptive of the modern process.

The usual mode of manufacturing copperas on the Rivers Tyne and Wear, is by exposing iron pyrites, (there called *brasses*.) which are found in the collieries, to the influence of the atmosphere. For this purpose, a situation is chosen, inclining towards the river, of a natural strong clay. After the soil is taken off, gutters are cut in different directions, and wells of about five or six feet deep and two or three in diameter are sunk where the gutters terminate. Upon this surface the brasses are laid to the thickness of four or five feet. The vitriolization shows itself in a white efflorescence, which is washed off by the rain into the gutters, and conveyed by pipes from the wells to a reservoir, from which there is a pipe of communication to the boiler. This is a leaden vessel generally about seven feet deep, twelve or fourteen long, and six or seven wide. Here the liquor is evaporated for six days, during which time as much of old iron is added to it as it will dissolve. It is then run into a crystallizing vessel, and remains there for five weeks, at the end of which time the mother-liquor is run into a reservoir, and pumped back into the boiler, the crystals being removed, which after being drained are packed in hogsheads for sale. A single boiling from a boiler of the above dimensions yields from five to eight tons of copperas, according to the strength of the liquor.

In 1830, an account was published in the *Repertory of Arts*, vol. liv., describing the principles of a French patent for the manufacture of this salt, but we are not aware that any works founded upon it have been adopted in this Country.

Vinegar Works.

Manufac-
ture of
vinegar.

(631.) *Vinegar* was, doubtless, as its name imports, first made from wine, and is always so made in wine Countries. It is there prepared by adding wine lees to wine, which excites a new fermentation that is kept up till the whole is changed to vinegar; but in this Country vinegar is generally made from malt, the usual process being as follows.

A mash of malt and hot water is made, which, after infusion for an hour and a half, is conveyed into coolers a few inches deep, and thence, when sufficiently cooled, into large and deep fermenting tuns, in which it is mixed with yeast, and kept in fermentation for four or five days. The liquor (which is now a strong ale without hops) is then distributed into smaller barrels, set close together in a stoved chamber, and a moderate heat is kept up for about six weeks, during which the fermentation goes on equally and uniformly till the whole is soured. This is then emptied into common barrels, which are set in rows (often of many hundreds) in a field in the open air, the bung-hole being just covered with a tile to keep off the wet, but to allow a free admission of air. Here

the liquor remains for four or five months, according to the heat of the weather, a gentle fermentation being kept up till it becomes perfect vinegar. This is finished in the following way. Large tuns are employed with a false bottom, on which is put a quantity of the refuse of raisins or other fruit left by the makers of raisin and other home-made wines, technically called *rape*. These rape tuns are worked by pairs; one of them is quite filled with the vinegar from the barrels, and the other is only three-quarters full, so that the fermentation is excited more easily in the latter than in the former, and every day a portion of the vinegar is laded from one to the other till the whole is completely finished and fit for sale.

Vinegar, as well as fruit wines, is often made in small quantities for domestic uses, and the process is by no means difficult. The materials may be either brown sugar and water alone, or sugar with raisins, currants, and especially ripe gooseberries. These should be mixed in the proportions which would give a strong wine put into a small barrel, which it should fill about three-fourths, and the bung-hole should be very loosely stopped. Some yeast, or what is better, a toast sopped in yeast should be put in, and the barrel set in the sun in summer, or a little way from a fire in winter, and the fermentation will soon begin. This should be kept up constant but very moderate, till the taste and smell indicate that the vinegar is complete. It should then be poured off clear and bottled carefully, and it will keep much better if it is boiled for a minute, cooled and strained before bottling.

The following is the quantity of British vinegar made and paying duty from 1820 to 1831:

Years.	Number of Gallons.	Amount of Duty.
1820	2,497,468	£40,586
1821	2,754,004	43,802
1822	2,004,639	45,638
1823	2,406,563	47,124
1824	2,360,426	46,341
1825	2,340,812	45,518
1826	3,028,891	25,136
1827	2,967,864	24,746
1828	2,652,867	24,475
1829	2,558,798	22,541
1830	2,159,858	17,862
1831	2,689,747	19,313

Whale Oil Works.

(632.) Amongst the various objects of British manufacture, and resting on British enterprise, the whale fisheries are by no means unimportant. The fishery itself is a subject of great interest, and is described with great perspicuity by Mr. Scoresby, in his *Account of the Arctic Regions*, published in 1820. It is, however, not within our limits to enter into a description of this first process towards obtaining the oil. We must consider the fish as already caught and stowed in the whale ships, and that these have returned to port with their blubber to be converted into oil fit for use. For the following description of this process we are indebted to vol. ii. of Mr. Scoresby's Work above referred to.

Description of the premises, apparatus, &c.—On the margin of a wet-dock, canal, or other sheet of water, communicating with that wherein the whale-fishing ship discharges her cargo, are usually provided the necessary

Mechanical
Processes.

Description
of premises
and appa-
tus.

Manufac-
tures.

Copper.

premises for reducing the blubber into oil, consisting commonly of the following articles.

A copper vessel or boiler, from three to six, or even ten or more tons capacity, of a circular form in the horizontal view, and elliptical in the perpendicular section, is fixed at the elevation of six to ten feet above the ground, provided with an approximate furnace, and covered with a tiled or slated shed. Some of these *coppers* have a sudden depression in the bottom, into which the refuse of the blubber subsides when it is sufficiently boiled; and at the elevation of a foot or eighteen inches above the bottom, (higher than the cavity usually occupied by the refuse,) is a grating and conducting pipe, through which, on turning a stop-cock, the greater part of the oil in the copper is conveyed into an adjoining cooler.

Back.

On the same, or on a little lower level than that of the copper, is fixed a square or oblong *back* or cooler, built generally of wood, but sometimes of brick or stone lined with lead or cement, capable of containing from ten to twenty tons of oil or upwards. Adjoining to this is another back, sometimes a third, and occasionally a fourth or fifth, each placed a little lower than the one preceding it, so that the lowest shall stand with its base about two or three feet above the level of the ground. In some very modern works, the coolers are all fixed at the same elevation. Each of the backs is provided with one or more stop-cocks on the most accessible side for convenience of drawing the oil off into casks.

Starting
back.

Altogether above the level of the copper, and immediately adjoining it, on the side directed towards the river or canal, an oblong wooden cistern, called the *starting back*, is usually erected, for containing blubber, which ought to be a vessel of equal or nearly equal capacity to that of the copper. It is generally provided with a crane, which, with a winch, or other similar engine attached, is so contrived as to take casks, either from the quay or from a lighter by the side of the quay, and convey them at once to the top of the starting back. Over this vessel is extended a kind of railing or *gauntree*, on which the casks rest, without being injured, and are easily movable.

The starting back being elevated two or three yards above the level of the ground, occasionally admits of a *fenk back* or depository for the refuse of the blubber immediately beneath it, which *fenk back* is sometimes provided with a *claugh* on the side next to the water for *starting* the fenks into a barge or lighter placed below. In some extensive premises, however, the fenks are deposited in a large shallow cistern or pit sunk into the earth, and made sufficiently large to contain the whole refuse of one cargo; where it remains undisturbed until the action of the sun extracts the remaining oil and brings it to the surface.

The premises likewise comprise a shed for the cooper, and sometimes a cooper's or master boiler's dwelling-house; the inhabitant of which takes the charge of all the blubber, oil, whalebone, and other articles deposited around him.

Warehouses for containing the oil after it is drawn off into casks are also used, not only for preserving it in safe custody, but for defending the casks from the rays of the sun, otherwise they are apt to pine and become leaky.

Sometimes a *steeping back* and apparatus for preparing whalebone are comprised within the same enclosure.

(633.) *Process of boiling.*—The blubber, which was

originally in the state of firm fat, is found on arrival in a warm climate to be in a great measure resolved into oil. The casks containing the blubber are conveyed, by the mechanical apparatus above-mentioned, to the top of the starting back, into which their contents are emptied or *started*, through the bungholes.

Mechanical
Processes.
Process of
boiling.

When the copper is properly cleansed, the contents of the starting back, on lifting a *claugh* at the extremity, or turning a stop-cock, fall directly into the copper, one edge of which is usually placed beneath.

In the premises of William Mellish, Esq., Shadwell Docks, London, which are the best adapted of any which Mr. Scoresby had seen, the starting back, which is about ten tons in capacity, has a false bottom full of small holes, placed a few inches above the true bottom, by which the oil is drained off, and passes through a grating and conducting pipe into an adjoining copper, and is boiled by itself, while the fenks collected by the grating are, at the same time, boiled in another copper placed equally convenient.

The copper is filled within two or three inches of the top, a little space being requisite to admit of the expansion of the oil when heated; and then a brisk fire is applied in the furnace and continued until the oil begins to boil. This effect usually takes place in less than two hours. Many of the fritters or fenks float on the surface of the oil before it is heated, but after it is boiled off, the whole, or nearly so, subsides to the bottom. From the time the copper begins to warm until it is boiled off or ceases to boil, the contents must be incessantly stirred by means of a pole, armed with a kind of broad blunt chisel, to prevent the fenks from adhering to the bottom or sides of the vessel. When once the contents of the copper boil, the fire in the furnace is immediately reduced, and shortly afterwards altogether withdrawn. Some persons allow the copper to boil an hour, others during two or three hours. The former practice is supposed to produce finer and paler oil, the latter a greater quantity. The same copper is usually boiled twice in every twenty-four hours, Sundays excepted. Supposing the copper to be filled at four in the morning, it is generally brought to boil by half-past five, and boiled off at half-past six or seven. It then stands to cool or subside until about two o'clock in the afternoon, when the *boiling* process commences. One of the backs or coolers having been prepared for the reception of oil, by putting into it a quantity of water, for the double purpose of preventing the heat of the oil from warping or rending the back, and for receiving any impurities which it may happen to hold in suspension, a wooden spout, with a large square box-like head, which head is filled with brushwood or broom that it may act as a filter, is then placed along from the *copper head* to the cooler, so as to form a communication between the two. The oil in the copper being now separated from the fenks, water, and other impurities, all of which have subsided to the bottom, is, in a great measure, run off through the pipe communicating with the cooler, and the remainder is carefully lifted in copper or tin ladles, and poured upon the broom in the spout, from whence it runs into the same cooler, at the pleasure of the *boilers*. Besides oil and fenks, the blubber of the whale likewise affords a considerable quantity of watery liquor, produced probably from the putrescence of the blood, on the surface of which some of the fenks, and all the greasy animal matter called *footje* or *footing*, float, and upon the top of these the oil. Great care,

Manufac-
tures.

therefore, is requisite on approaching these impure substances to take the oil off by means of shallow tinned iron or copper ladles, called *skimmers*, without disturbing the refuse and mixing it with the oil. There must always, however, be a small quantity towards the conclusion, which is a mixture of oil and footing; such is put into a cask or other suitable vessel by itself, and when the grosser part has thoroughly subsided, the most pure part is skimmed off, and becomes fine oil, and the impure is allowed to accumulate by itself in another vessel, where, in the end, it affords *brown oil*.

The refuse now left in the copper is *bailed* into a tunnel or spout, which conveys it into the fenk back, where it remains as long as the capacity of the vessel will admit; a portion of brown oil, which is constantly found rising to the surface, being in the mean time occasionally skimmed off.

A few years ago Mr. Scoresby, sen. instituted a process for reducing blubber into oil, by the use of steam; and a similar process has been adopted in Hull and other ports, and applied to the extraction of oil, with considerable advantage.

Product.

From a tun, or 252 gallons by measure, of blubber, there generally arise from 50 to 65 gallons of refuse, whereof the greater part is a watery fluid. The constant presence of this fluid, which boils at a much lower temperature than the oil, prevents the oil itself from boiling, which is, probably, an advantage, since, in the event of the oil being boiled, some of the finest and most inflammable parts would fly off in the form of vapour; whereas the principal part of the steam which now escapes is produced from the water. Some persons make a practice of adding a quantity of water, amounting, perhaps, to half a tun, to the contents of each copper, with the view of weakening or attenuating the viscid impurities contained in the blubber, and thus obtaining a finer oil; others consider the quantity of water already fluid in the blubber as sufficient for producing every needful effect.

Preparation
for repeat-
ing the
process.

Each day, immediately after the copper is emptied, and while it is yet hot, the men employed in the manufacture of the oil having their feet defended by strong leathern or wooden shoes descend into it, and scour it out with sand and water, until they restore the natural surface of the copper wherever it is discoloured. This serves to preserve the oil from becoming high coloured, which will always be the case when proper cleanliness is not observed.

The starting back being previously filled with blubber, its contents are again transferred into the copper, and the fire is applied as before. This is generally accomplished by four or half-past four o'clock in the afternoon. The copper again boils by half an hour after five or six, and is boiled off by seven or eight in the evening. The men employed in this service, consisting of about six persons, alternately watch in the night by couples. Those on watch commence about two in the morning to empty the copper, which done, they again fill it from the starting back, which is always made ready the night before. Thus the process goes on until the whole cargo is finished.

By means of three coolers severally capable of containing at least twice the quantity of oil produced from one boiling of blubber in the copper, each can be allowed, in turn, to stand undisturbed upwards of twenty-four hours. Thus while one is being filled, another stands to cool and settle, and the third is drawn off. If the

backs be twice the size, or four times the capacity of the copper, the oil, after being filled, may be allowed to subside during two or three days. Even two backs in number of this capacity would admit of an interval of twenty-four hours each, after being filled, before it would be necessary to begin to empty it.

Thus prepared and cooled, the oil is in a marketable state, and requires only to be transferred from the coolers into casks for the convenience of conveyance to any part of the country. Each of the coolers, it has been observed, is furnished with a stop-cock, beneath which there is a platform adapted for receiving the casks, where they are filled with ease by the introduction of a leathern tube extending from the orifice of the stop-cock into the bung-hole. At the conclusion of the process of boiling each vessel's cargo manufactured on the premises, the backs are completely emptied of their contents. To effect this, water is poured in until the lower part of the stratum of oil rises to within a few lines of the level of the stop-cock, and permits the greater part of the oil to escape: the quantity left amounts, perhaps, to half an inch or an inch in depth. To recover this oil without waste requires a little address. A deal board, in length a little exceeding the breadth of the cooler, is introduced at one end a little diagonally, and placed edgeways in its contents. The ends of the board being covered with flannel, when pressed forcibly against the two opposite sides of the cooler, prevent the oil from circulating past. The board is then advanced slowly forward towards the part of the back where the stop-cock is placed; and in its progress (the ends being kept close to the sides of the cooler, and the upper edge a little above the surface of the oil) all the oil is collected by the board, while the water has a free circulation beneath it. When the oil accumulates to the depth of the board, its further motion is suspended, until the oil thus collected is drawn off. Another similar board is afterwards introduced at the furthest extremity of the cooler, and passed forwards in the same manner, whereby the little oil which escapes the first is collected. Now the remnant which still refuses to run off by the orifice of the stop-cock being collected in a corner, is taken up by the *skimmers*, and the footing or cement which appears at the last is disposed of in the same way as the footing from the copper until the oil it contains rises to the surface and can be removed.

In most of the outports, the oil is generally deposited in casks, in which it remains until it is disposed of by the importers. In London, however, and in some concerns in Hull and other ports, the speculators in the whale fishery are provided with cisterns or tanks, wherein they can deposit their oil, and preserve it until a convenient time for selling, without being subject to the waste which usually takes place when it is put into casks. From these cisterns any quantity can be drawn off at pleasure.

The smell of oil during its extraction is undoubtedly disagreeable, but perhaps not more so than the vapour arising from any other animal substance submitted to the action of heat when in a putrid state. The prevailing opinion, however, that a whale ship must always give out the same unpleasant smell is quite erroneous. The fact is, that the fat of the whale, in its fresh state, has no offensive flavour whatever, and never becomes disagreeable until it is brought into a warm climate and becomes putrid; neither is a whale ship more unpleasant than any other trader, until after her cargo is

tures.

Preparation
of whale-
bone.

opened on her arrival in port. Scoresby, *Arctic Regions*, vol. ii.

(634.) *Preparation of whalebone.*—Whalebone, or whale fins, as the substance is sometimes, though incorrectly, named, is found in the mouth of the common Greenland whale, to which it serves as a substitute for teeth. It forms an apparatus most admirably adapted as a filter for separating the minute animals on which the whale feeds from the sea water in which they exist.

It is a substance of a horny appearance and consistence, extremely flexible and elastic, generally of a bluish-black colour, but not unfrequently striped longitudinally with white, and exhibiting a beautiful play of colour on the surface. Internally it is of a fibrous texture, resembling hair; and the external surface consists of a smooth enamel, capable of receiving a good polish.

This substance when taken from the whale consists of laminæ, connected by what is called the *gum* in a parallel series, and ranged along each side of the mouth of the animal. The laminæ are about 300 in number in each side of the head. The length of the longest blade, which occurs near the middle of the series, is the criterion fixed on by the fishers for designating the size of the fish. The greatest length is about 15 feet; but an instance very rarely occurs of any being met with above $12\frac{1}{2}$ or 13 feet. Its greatest breadth, which is at the root end, is 10 or 12 inches, and its greatest thickness $\frac{4}{10}$ or $\frac{5}{10}$ of an inch.

The two sides or series of the whalebone are connected at the upper part of the head or crown bone of the fish, within a few inches of each other, from whence they hang downwards, diverging so far as to enclose the tongue between their extremities; the position of the blades with regard to each other resembles a frame of saws in a saw-mill; and taken altogether, they exhibit in some measure the form and position of the roof of a house. The smaller extremity and interior edge of each blade of bone, or the edge annexed to the tongue, are covered with a long fringe of hair consisting of a similar kind of substance similar to that constituting the interior of the bone.

Whalebone is generally brought from Greenland in the same state as when taken from the fish, after being divided into portable *junks* or pieces, comprising 10 or 12 laminæ in each; but, occasionally, it is subdivided into separate blades, and the gum and hair removed when at sea.

One of the first importations of whalebone into England was probably in the year 1594, when a quantity of this substance, being part of the cargo of a wrecked Biscayan ship, was picked up at Cape Breton by some English ships fitted out for the whale and morse fisheries, after the example of the Icelanders and Biscayans.

This substance has been held in so high estimation, that since the establishment of the Spitzbergen whale

fishery the British have occasionally purchased it of the Dutch at the rate of £700 *per ton*. It is calculated that at least £100,000 *per annum* were paid to the Dutch for this article about the year 1715 or 1721, when the price was £400. About the year 1763 the price in England was £500 *per ton*; but after an extensive importation of this article from New England, the price declined to £350, and subsequently as low as £50 *per ton*. Of late years the price has usually been fluctuating between £50 and £150 *per ton*. Whalebone becomes more valuable as it increases in length and thickness.

On or near the premises in which the oil is extracted the whalebone is commonly cleaned and prepared. The first operation, if not already done, consists of depriving it of the gum. It is then put into a cistern containing water, until the dirt upon its surface becomes soft. When this effect is sufficiently produced, it is taken out, piece by piece, laid on a plank placed on the ground where the operator stands, and scrubbed or scoured with sand and water, by means of a broom or a piece of cloth. It is then passed to another person who, on a plank or bench, elevated to a convenient height, scrapes the root end where the gum was attached until he produces a smooth surface; he or another workman then applies a knife or a pair of shears to the edge, and completely detaches all the fringe of hair connected with it. Another person, who is generally the superintendent of the concern, afterwards receives it, washes it in a vessel of clean water, and removes with a bit of wood the impurities out of the cavities of the root. Thus cleansed, it is exposed to the air and sun until thoroughly dry, when it is removed into a warehouse, or other place of safety and shelter.

Before it is offered for sale, it is usually scrubbed with brushes and haircloth, by which the surface receives a polish, and all dirt or dust adhering to it is removed; and, finally, it is packed in portable bundles, consisting of about a hundred weight each. The *size* bone, or such pieces as measure six feet or upwards in length, is kept separate from *under size*, the latter being usually sold at half the price of the former. Each blade being terminated with a quantity of hair, there is sometimes a difficulty in deciding whether some blades of whalebone are *size* or not. Owing to the diminished value of *under size* bone, and more particularly in consequence of the captain and some officers engaged in a fishing ship having a premium on every size fish, it becomes a matter of some importance in a doubtful case to decide this point. From a decision which has been made in a Court of Law, it is now a generally received rule, that so much of the substance terminating each blade as gives rise to two or more hairs is whalebone; though, in fact, the hair itself is actually the same substance as that of which the whalebone is composed. See the Work above quoted.

Works employed in the Formation of artificial Substances.

(636.) In the two preceding sections we have treated, first, of the reduction of metallic ores to the purely metal form, and, secondly, of the formation of salts, acids, &c., by the natural affinities of their several components. We now propose to describe those artificial compounds produced by fusion or otherwise, which are of such extensive use in the Arts, and important to the conveniences and luxuries of civilized Society; such as bricks, pottery, porcelain, glass, &c.

Brick Works.

History of bricks.

(637.) It has been questioned which of the two sister Arts, brick-making or pottery, is the most ancient; although it is generally admitted that they both are amongst the earliest efforts of human ingenuity. Bricks are frequently mentioned in the early History of the Old Testament, as is also the potter's wheel: we should, however, be inclined, from the simple process in the one case, compared with the artificial means necessary in the other, to decide in favour of the Art of Brick-making. The walls of Babylon were unquestionably built with brick, and unburned bricks were employed in many of the antique buildings in Egypt. Several, indeed, of the Pyramids and edifices are of stone, but Pocock describes a Pyramid of unburned bricks, called "Kloube-el-Menshich," (the bricks of Menshich,) from a village near, called Menshich Dashour. It was doubtless built near the plain, on account of the bricks, which seem to be made of the earth brought by the Nile, being of a black sandy nature, with some pebbles and shells in them. It is

mixed up with chopped straw, in order to bind the clay together; as the inhabitants now make unburned bricks in Egypt and many other Eastern parts, which are used very much in their buildings. "I found," says the author, "some of these bricks $13\frac{1}{2}$ inches long, $6\frac{1}{2}$ inches broad, and 4 inches thick; and others 15 inches long, 7 inches broad, and $4\frac{3}{4}$ inches thick. I observed on the North side that the bricks were laid lengthways from North to South, but not every where in that direction; however, I particularly took notice that they were not laid so as to bind one another. It is much crumbled and ruined, but as it is I measured it, and found it to be 157 feet on the North side, and 210 feet on the West side; it is 150 feet high. By what I could judge, from the present slope of it, I concluded that it was built with five degrees, like the Pyramid of Saccara, each being about 10 feet broad and 30 deep, so that the ascent to it is easy, as the bricks are crumbled away."

Such is an account of the early unburned bricks of Egypt, and which are still in use: it does not appear, however, that brick-making in that Country is a distinct trade or occupation, the Art being practised by farmers, labourers, and tradesmen indifferently. The following account of the present practice, from No. X. of the *Architectural Magazine*, may, perhaps, be interesting to some of our readers.

"Near the bank of the Nile, or in any other place where water and rich soil may be found, one or two men go into the water, and with a rude instrument, like a carpenter's adze, they cut about two or more feet deep, six or eight feet long; the breadth is according to circumstances. After they have cut about a load of soil, they mix with it one sack full of broken straw, cut about a quarter of an inch long, (the quantity of this material

Method of making bricks in Egypt.

Manufactures.

must be proportioned to the quality of the soil,) and a certain quantity of ashes. After these materials are well mixed together, they are ready for moulding. One man takes a *barrshane* and goes to the other who is in the pit, who fills it up with the mixture; and then the first carries it to a barren place or common. When a sufficient quantity has been carried to this place, the labourers spread the cut straw over the ground where the bricks are to be made. The brick-makers then get each of them a vessel full of water, and then sit each to his work. They fill the moulds with their hands, and when each mould is full, they dip their hands into the water, and pass them over the surface of the brick to smooth it; and then taking up the mould they leave the brick on the ground to dry, and so on. When the desired quantity of bricks are made, they are left to harden in the sun; and when they become dry on the upper surface, they are turned over till they become thoroughly dry and hard enough for immediate use, or for burning."

Bricks of the Greeks and Romans.

The Greeks and Romans, although they were not unacquainted with the Art of burning bricks, yet they also employed unburned bricks, for the making of which Vitruvius gives the following directions: "They should not," he observes, "be made of stony, sandy, or gravelly loam, for such kind of earth renders them heavy; and upon being wetted with rain after being laid in the wall, they swell and dissolve, and the straw which is put in them does not adhere on account of their roughness. The earth of which they are formed should be light chalky white or red. They should be made in Spring or Autumn, as being the best time for drying; for the intense heat of Summer parches the outside before the inside is dry; which afterwards drying in the building, causes them to shrink and break. They are best when made two years before they are used, as they cannot be sufficiently dry in less time. If they are used when newly made and moist, the plaster-work which is laid on them will remain firm and stiff, but the bricks shrink, and, consequently, not preserving the same height with the incrustation, it is by such contraction loosened and separated. At Utica, therefore, the law allowed no bricks to be used before they had lain to dry five years."

Proper earth for bricks.

The earth proper for making bricks is a clayey loam, neither abounding too much with sand, which renders them brittle, nor with too large a portion of argillaceous matter, which causes them to shrink and crack in drying. As the earth before it is wrought is generally brittle, and full of extraneous matter, it should be dug two or three years before it is used, so that, by being exposed to the action of the atmosphere, it may be sufficiently mellowed and pulverized, and thus facilitate the operation of tempering. At any rate it should always have one Winter's frost; but the longer it lies exposed, and the more it is turned over and wrought with the spade, the better will be the bricks.

Tempering the clay.

The tempering of the clay was formerly, and is still, in some places, performed by the treading of men or oxen, but it is now most commonly effected by means of a clay or pug-mill, consisting of a large vertical cone, having strong knives with a spiral arrangement and inclination fixed on its internal surface. Passing through the centre, and terminating in a pivot at the bottom, is a strong perpendicular shaft with similar radiating knives, so that the knives, by the revolution of the shaft, cut, separate, and mix the clay, till it is reduced to a homogeneous paste, which passes through an orifice at the bottom into a receiver placed for that purpose.

The clay is then taken from the receiver to the moulder's bench, and is, either by a lad or a woman, cut into pieces somewhat larger than the mould, and passed on to the moulder, who works it into a mould, previously dipped in sand, and strikes off the superfluous parts with a flat smooth piece of wood. In this Country, the mould used is about 10 inches in length and 5 inches in breadth, and the bricks when burned are about 9 inches long, $4\frac{1}{2}$ inches broad, and $2\frac{1}{2}$ inches thick. The degree of shrinking, however, is various, according to the temper and purity of the clay, and the degree of heat attained in the burning. A handy moulder is calculated to mould from 5000 to 7000 per day.

Mechanical Processes. Moulding.

From the moulder's bench the bricks are carried to the stack, and arranged somewhat diagonally, one above the other, and two edgewise across, with a passage between the heads of each for the admission of air, till they are eight bricks in height. They are then left to dry. The time they take before they require shifting depends entirely upon the weather, which, when fine, will be but a few days; they are then turned and reset wider apart, and in six or eight days are ready for the clamp or kiln.

(638.) *Burning the bricks*, which is the next operation, is performed either in a kiln or in a clamp. In the former the bricks being set, and the kiln covered with pieces of the same, a gentle fire of wood is made to dry them; and this is kept up until they are pretty dry, which is known by the smoke turning from a whitish to a thin black smoke. Wood is then no longer used, but in its stead brush, furze, straw, brake, or fern faggots are employed. Having first closed up the mouth of the kiln with a thin log, (or pieces of brick piled upon one another, and closed with wet brick earth instead of mortar,) more faggots are used till the kiln and its arches look white, and the fire appears at the top, upon which the latter is slackened for an hour, and left to cool by degrees. Thus the workmen continue alternately heating and slackening till the bricks be thoroughly burned, which is usually effected in forty-eight hours.

Burning.

Clamps are generally employed about London, which are built of the bricks themselves, after the manner of arches in kilns, with a vacancy between each of a brick's breadth, for the fire to play through; but with this difference, that, instead of arching, the flues are gathered over by making the bricks project over one another. The place for the fuel is carried up straight on both sides till about three feet high; it is then nearly filled with wood, and over that a stratum of sea coal, and then the earth; sea coal is also strewed between every row of bricks in the clamp; lastly, the wood is kindled which communicates with the coals, and when all is exhausted the bricks are considered to be sufficiently burned.

The proper burning of bricks is a matter of considerable difficulty, and requires an experienced workman; as it is necessary to maintain an equal heat throughout the whole mass, neither too little, which would leave the bricks weak and crumbly, nor too great, which would cause them to run together into a vitrified slag. The operation is for this reason much better performed in kilns than in clamps, as the fire can be kept up and regulated at discretion; while in clamps, as the whole of the fuel must be put in at once, the manufacturer is always tempted to use too little, and the outside bricks are necessarily under-burned. These are called *samel* bricks, and are sold at an inferior price.

Manufac-
tures.

The different kinds of bricks made in this Country are principally *place bricks*, *grey* and *red stocks*, *marle facing bricks*, and *cutting bricks*. The *place bricks* and *stocks* are used in common walling. The *marles* are made in the neighbourhood of London, and used in the outside of buildings; these are very beautiful bricks, of a fine yellow colour, hard, and well burned, and in every respect superior to the *stocks*. The finest kind of *marle* and *red bricks* are called *cutting bricks*; they are used in the arches over windows and doors, being rubbed to a centre and gauged to a height. There is also a fine kind of white bricks made near Ipswich, which are used for facing, and sometimes brought to London for that purpose. The *Windsor bricks* or *fire-bricks*, which are made at Hedgerley, a village near Windsor, are red bricks, containing a very large proportion of sand; these are used for coating furnaces, and lining the ovens of glass-houses, where they stand the utmost fury of the fire. *Dutch clinkers* are also imported; these are long narrow bricks of a brimstone colour, very hard and well burned; they are frequently warped, and almost always vitrified. The use of them is for paving yards and stables.

Duty on
bricks.

(639.) *Duty on bricks*.—By 17 Geo. III. c. 42. all bricks made for sale shall, when burned, be not less than $8\frac{1}{2}$ inches long, $2\frac{1}{2}$ thick, and 4 inches wide.

By 43 George III. c. 69. (consolidating the Excise duties,) passed July 4, 1803, every thousand of bricks made in Great Britain, not exceeding 10 inches long, 3 inches thick, and 5 inches wide, are liable to a duty of five shillings, and exceeding the aforesaid dimensions to ten shillings; and every thousand of bricks made in Great Britain, and smoothed and polished on one or more sides, not exceeding the superficial dimensions of 10 inches long by 5 inches wide, are subject to a duty of twelve shillings, and if such bricks exceed these dimensions, to the duty on paving tiles. The said duties are to be paid by the makers. An additional duty of tenpence per thousand was imposed on bricks and tiles in the Ways and Means for the year 1805.

The policy of the tax on bricks has always been much questioned, not merely as regards the amount, but as placing the maker under inconvenient restrictions. On this head Mr. Bakewell, in his Treatise on brick-making, observes: by the 17 Geo. III. c. 42. bricks made for sale in England must be $8\frac{1}{2}$ inches long, $2\frac{1}{2}$ inches thick, and 4 wide; the size of the sieves for sifting coal ashes to mix with the clay must not exceed a quarter of an inch between the meshes; the reader, however, will see most clearly the onerous nature of the laws governing this simple branch of rural employment in the following paragraph.

Notice must be given of the intention to begin *making* under the penalty of £100; the size, the form, and, it may be said, the quality of the article, is prescribed, and the size of the sieve is fixed. The articles are chargeable with the duty, (subject to an allowance of ten in the one hundred for waste,) directly as they come from the mould. From the nature of the manufacture, this is, however, insufficient, and the same raw material may have to pay the duty several successive times; for as all the processes take place in the open air, the article is liable to be injured, or even destroyed, by heat, by cold, or by rain; and when a batch has successfully escaped the elements, there is still the ordeal of the kiln. Thus when the bricks on leaving the mould are *set up*, they may be destroyed by frost in a single night. After reworking and repaving they may be washed away, or

otherwise damaged, by a storm or land flood. If the material, or any part of it, is again reworked, the duty is again levied, and the bricks are placed in *clamp*; where they may, from accident, turn out *shaky*, or be altogether spoiled. For natural risks, the consumers of a manufacture must of course pay; but in the present case the premium of insurance is very greatly raised by the tax, while the risk itself is very greatly increased by the regulations. For instance, when the bricks are once *set up*, there they must remain till the officer has brought them to charge, or, what is virtually the same, has given permission to remove them, although their non-removal should subject them to be injured or destroyed. Every spot on which they are placed during the process of a manufacture must be entered. If from accident, carelessness, or design, they are put in an unentered place, the maker is subjected to the penalty of £50. After all, the duty only yields £365,000, and from which there is to be deducted the expense of the collection. This is very considerable, for brick fields are scattered all over the country, and frequently established for temporary purposes; as when houses are to be erected in a remote neighbourhood, or when brick earth is found upon the intended site, and the builder turns brick-maker, probably at a considerable distance from any Excise station.

Mechanical
Processes.

Pottery.

(641.) The potter's Art seems to have been nearly coeval with civilized Society. It was undoubtedly in the earliest stages of a very inferior quality; but the Egyptians, Greeks, and Romans possessed it in a high state of perfection, and the Chinese have been celebrated for their ware from the earliest periods of their History. Common pottery has also been known and practised for many Ages by all European nations; but it was only at the commencement of the last century that it began to assume a scientific character, first in Dresden, then in Holland, France, Germany, and England; and in this Country during the last half century it has made a progress so extraordinary as at this day to rival, if not to surpass the works of any nation, not excepting the Chinese. Our limits will not admit of our following out the details of its history, because we are desirous

Manufactures. of entering at as great a length as possible into a description of interesting particulars connected with its manufacture, with which we have been kindly furnished by a gentleman resident in the Potteries, who has very carefully attended to every manipulation connected with the Art.

Terms defined.—The manufacture of ductile earths into vessels of capacity for the various purposes of the table and the toilet, also into ornamental figures, vases, busts, and bas reliefs, enhanced in value by their elegance and durability, is technically named *potting*; the suite of erections for carrying forward the processes and operations, a *pottery*; and the manufactured articles according to their nature and quality, the finest and semi-transparent, *porcelain* or china, the completely opaque but fine, *earthen ware*, *flint ware*, *queen's ware*, *delft ware*, &c., and the coarser kinds, *stone ware* and *pottery*.

Porcelain.

Different descriptions of ware

(642.) The finest branch of this manufacture includes two kinds, from their components named *hard* and *soft*. The former constantly, the other partially, when fractured, exhibits a texture and grain compact, is hard, firm, dense, durable, and semi-vitreous; when struck by a hard body is sonorous; in appearance is white or milk colour, semi-transparent, and intermediate between the closeness of glass and the obvious porosity of the best flint pottery; is covered with a transparent glaze, smooth, fine, clear, white, and not affected by acids or alkalis; and sustains, without failing, sudden alternations of temperature. These are essential properties.

Pottery of the best kind.—Flint ware or queen's ware, delft ware, (and the word is also applied to coarse common ware,) for the table, the toilet, and various domestic purposes, has coarser texture and grain than porcelain; is not semi-transparent, nor vitreous, though firm, hard, sonorous, durable, and covered with a rich vitreous glaze, not affected by acids, alkalis, or sudden alternations of temperature. Also including that very important branch,

Chemical utensils, such as alembics, crucibles, dishes, retorts, tubes, and many other implements indispensable in the laboratory.

The manufacturer's chief object of attention is, to compound his materials with so strict a regard to chemical science, as will ensure to his ware certain essential and indispensable qualities.

Hard porcelain.—With a body very dense and durable, fracture vitreous, white, semi-transparent, sonorous when struck by a hard body, and with a clear indestructible glaze, smooth to the touch, beautifully fine, appearing soft like velvet, rather than lustrous or glossy like satin, resisting the action of acids and alkalis, and uninjured by alternations of temperature.

Soft porcelain.—Body less dense, yet sonorous, granular, and very fine porous fracture, harder and less brittle than glass, white, semi-transparent, moderately hard glaze, and will bear considerable alternations of temperature.

Flint ware.—Body in texture and grain moderately dense, porous fracture, sonorous when struck, with glaze fine, clear, free from specks, transparent to show the ornamental designs made on the biscuit, not affected by acids, alkalis, or sudden alternations of temperature.

The Dresden porcelain, equally fixed and infusible as

the Japanese, is in some qualities decidedly superior; it is firm and compact, and will sustain without injury sudden change of temperature; its fracture is not granular but uniform, and similar to white enamel. Its fusible components are from the tarso of the river Po; and its infusible is the clay from Aue, near Schneeberg; which Rose states to contain silica 52, alumine 47, iron 0.33. But these are not chemically equivalent, and some error perhaps exists in the analysis. When these substances are combined, in proportions not here ascertained, the felspar gravel, by its fusibility, promotes the density, smoothness, and superior lustre, while the clay gives to it its firm solidity and beautiful white appearance; and together there is regular contraction during the process of baking.

The porcelain of Berlin is formed of the tarso, and clay from the valley of Gatach, above Haussach, in Wirtemberg; those of Vienna, Frankendal, and other places in Germany, of the tarso, and clay from near Passau; but there is such variation in the proportion, or the process, or both, as to cause considerable difference, as well from the Dresden, as from each other. And equal difference exists between those of Villaroy and Orleans, of Naples and Florence (the latter resembling the best qualities of the Oriental); these use the felspar and clay from Alençon, and St. Yrieux la Perche, near Limoges, and some from near Bayonne.

The Sevres porcelain excels all the others manufactured in France; (although great improvement has been made therein;) in its fracture it is more like very fine lump sugar than a vitrified substance, has all the other properties of true porcelain, and is covered with a glaze colourless and transparent. The proper components are, for the body, felspar 67, clay 33; and for the glaze, felspar 85, potass 15. Other numbers and substances have been given; as clay 66, felspar 15, sulphate of lime 9, whiting 6, ground pieces of ware 10; glaze, melting spar 75, sulphate of lime 12, and ground ware 12; but we believe those assigned above are correct. The following comparison will probably supply useful information as well as gratify curiosity.

The *stone china*, in much demand for table and toilet services, is a very thick, strong, semi-transparent ware, coarse in texture, vitrescent, and granular in fracture, and durable, but with a glaze very soft compared with the Oriental porcelain it is intended to imitate. An addition of slag from the iron-smelting furnaces produces the kind called *patent ironstone china*.

The appellation of *dry bodies* is given to unglazed ware, of different colours, which is formed into elegant and valuable articles; several are so compact and highly vitrified as neither to require, nor indeed to receive a glaze; their surface presents minute pores from the fusion of the components, and their beauty is improved by absence of the vitreous coating, which prevents the sharpness of the fine lines appearing prominent; and however well adapted for utility, can never equal the

Mechanical Processes.

Manufac-
tures.

elegance of a polished surface. To this class belong the wine-coolers or *alcarazas*, formed of a size sufficiently large to admit a bottle within the cylindrical part, and ornamented on the outside. Butter coolers are smaller in size. The components are only partially baked, and yet sufficiently adhesive to sustain without injury the constant oozing of the water through them on all sides. After being filled with water till the pores are saturated, the bottle is put in, and the action of the surrounding air on the water, as it evaporates outside, induces such a reduction of temperature as affects completely the contents of the bottle.

The *chemical utensils* body is adapted to sustain, uninjured, the action of different powerful agents; and very recently the younger Josiah Wedgwood, of Etruria, has greatly improved this important article of the Chemist's laboratory. Certainly no compound wherein silica is present can completely resist the action of all chemical preparations; but as far as possible this should be counteracted by suitable components. All chemical action being in proportion to the exposed surfaces of the opposing substances, the greater the comminution of the silica in the vessels used for such fluents, the less opportunity will there be for destructive effect. How this great comminution is accomplished, will presently be mentioned.

Those chemical utensils which are intended to be subjected to the action of heat should be refractory at any temperature easily and usually applied; should bear saline and other fluxes in fusion without being permeated or injured thereby, and should neither crack nor fly by sudden application of heat, nor yet of cold when heated. How these valuable properties are secured to the ware is indispensably needful to be mentioned. The compound ascertained to be most refractory has a fourth part of baked ware again ground very fine, mixed with clays that are not spiced with lime, as this would promote the fusibility of the silica. It is probable that the practice has originated from a remark of the younger Pliny; (*Nat. Hist.* lib. xxxv. c. 12.) "Strong mortar or cement was made by the broken sherds of potters' vessels ground into powder and tempered with lime; which being firmer and lasting longer was called *signina*." The intermixture of ground pitchers is constantly practised in the Sevres manufactory; and when these are not at hand, an artificial substitute is prepared and ground. The French also grind up their old Normandy butter pots to mix with aluminous schist, and bake at extremely high heat for their crucibles. And our seggar-makers adopt the principle in their productions; as likewise do the makers of the glass-house crucibles, though extremely strong, and for this reason: unless the components will equally contract and expand together on change of temperature, and unless there be provision made in the compound for any slight excess of a refractory or of a fusible component, cracking will ensue; as has been proved innumerable times with even Wedgwood's best vessels, though slowly and gradually raised and coated with fire-lute, sand and clay, horse dung and tow, Windsor loam, and Cornish clay slip; therefore, when the fresh materials are mixed with the old in a state of impalpable powder, while the vessel will be compact and firm, little liable to be injured by acids or alkalis, there would be provision for the reaction of the fresh components on any rise of temperature. Crucibles for the fusion of metals only are made by mixing very intimately with the clay, carburet of iron, (black

lead,) which at all temperatures being infusible, and devoid of tendency to combine with the clay which protects it from the action of the atmosphere, is incombustible, and less than any other compound affected by the sudden changes of temperature; yet without retaining, as do the sides of other crucibles, any portion of the fused substances. Hessian crucibles, which are firm, compact, and at high heats retentive of saline fluxes, are formed by pressing with great force into an iron mould, a just moistened mixture of felspar, refractory clay three parts, and one part of coarse washed sand.

The *flint ware*, (technically named *earthen ware* and *pottery*,) like all the preceding, is a compound of different earths, well baked first, and then covered with a fusible white glaze or enamel. The kinds of flint ware differ much, according to the qualities and proportions of the earths used as components, in their firmness, and sustaining sudden changes of temperature without breaking; some of the best being easily affected by a brisk fire, and others, common and rather coarse, often remaining uninjured by it. They differ equally in the beauty and excellence of their glaze or enamel, figures, and methods of decoration.

The *Delft ware*, so named from the town in Holland at which it is made, first suggested the Staffordshire white stone ware, and flint ware followed. The delft is made of a compound of earths, clay alone not being proper, neither will pure clay answer. When the clay has excess of alumine, the workman calls it *too fat*; and vessels made of it, even though exceedingly thick, would require a long time to dry, lose their form, and crack by the natural escape of the water. To take away this fatness, still to preserve the mass sufficiently ductile and adhesive to bear the requisite manipulations of the thrower, turner, and presser, a quantity of sand or marl is added; the silica acidulates the excess of the alumine, and counteracts the usual tendency of the clay to shrink or contract, which cracks the vessel; the ware is rendered less compact, the water escapes without the ware being injured by the drying; while a compound of blue clay with marl only is not firm and solid for the purpose required, and the enamel scales off, as in the *overflinting* of flint ware, unless it is baked at a very high temperature; whereas the usual practice is to bake it slightly to prevent its sinking on applying the enamel; but when two or more clays are partially mixed, and sand or marl is added, the first baking supplies a proper ground for the enamel, which appears white and more glossy than on the other bodies. The components of the glaze, according to M. Bosc d'Antic, are for the common delft ware, calc of lead 46, calc of tin 6, fine sand 40, sea salt 8; for the best 38, 10, 40, 12, respectively.

Clay, in the manufacture, is the name of every different compound of earths, and *body* is that of the mass in reference to its properties, and as distinguished from its *glaze* covering. As each manufacturer endeavours to give distinction to his ware by some supposed excellence in mixing the several components, numerous different proportions are given in recipes, and consequently the relative qualities result from some factitious circumstances. Of the porcelains, some are white, beautifully semi-transparent, and smooth-glazed, yet will scarcely bear the manipulations, are easily fused in baking, light in weight, crack on rise of temperature, and the glaze so soft as to wear off, or become dull and rough; and others are greyish in colour, sustain

Manufactures.

Recipes for bodies and glazes.

the working, bake compact and dense at a very high heat, and are not injured by customary changes of temperature. The body has definite quantities of the Middleton Hill felspar and china clay of Cornwall; and the glaze likewise of fine felspar and alkali.

(643.) The following recipes produce *bodies* and *glazes*

differing in excellence in consequence of some factitious circumstances; they are, however, of general utility; and the results will be satisfactory when the materials are compounded in the manner directed. The Cornish stone is being rapidly superseded by the Middleton Hill kaolin for body, and the petuntse for glaze.

Glaze for No. 8, 9, and 10, *Blue Printing*. *Fritt*.—Glass 69, litharge 18, nitre 8, arsenic 4, cobalt blue 1.

Or, fritt 6, flint 14, Cornish stone 26, white lead 54.

Glaze for enamelling.—*Fritt* 5, flint 15, Cornish stone 25, litharge 55.

Glaze for 5 and 6, B. P. *Fritt*.—Glass 70, litharge 22, nitre 4, arsenic 4, blue calc 1.

Glaze for cream colour.—Glass 50, common glass 20, fritt 30. Grind well together.

Glaze for coloured.—*Fritt* 18, flint 10, stone 25, white lead 48.

Glaze for mocha.—*Fritt* 13, flint 11, stone 26, litharge 50.

Glaze for printing.—*Fritt* 12, flint 20, stone 23, litharge 45.

Glazes for 1, 2, 3, 11, 12, B. P.—Petuntse 66, barytes 12, boracic acid 18, common salt 3, nitre 1.

Or, petuntse 75, barytes 12, boracic acid 8, common salt 4, nitre 1.

Or, petuntse 65, barytes 14, boracic acid 18, common salt 1, nitre 2.

Or, petuntse 56, barytes 12, boracic acid 15, common salt 9, potass 8.

Or, petuntse 57, barytes 12, boracic acid 15, common salt 8, potass 8.

When the cream-coloured glaze has excess of borax, it is transparent and greenish-yellow; and the borax is of great power as a flux of the earths and metallic oxides; but being soluble in water, and efflorescent in air, defective chemical combination will present opportunity for *crazing* equally with imperfect combination of the components of the glaze with those of the body, or their unequal degree of fusibility, or insufficient baking, or excess of uncombined alkali, or exposure while hot in the oven to the current of air. Instead of borax, in coloured glazes, nitre is substituted, and, without affecting their fusibility, it promotes the high oxidation of the metals, and thereby improves the lustre of the colours. The nitre is decomposed by silica, alumine, and barytes, com-

binning with its base in the high heat while baking the glaze; but it is injurious in fluxes for blue, green, pink, or purple colours.

The tendencies and action of boracic acid are sluggish compared with those of other acids; it melts below red heat, yet this is requisite that it may flow freely; it is more refractory than borax, and when cool is hard, vitreous, and moderately transparent. Its rejection of alumine would, however, preclude its application in the manufacture, did not the very high heat of the oven particularly facilitate the fusion of the silica into a vitreous solid mass not alterable by the atmosphere, and render liquid the other earths present during the fusion; it also disperses all acids except the phosphoric, remaining unvolatilized by any heat usually applied in baking the glaze.

In lead glazes, arsenic has been used as a component of the fritt, under the idea that it rendered the glaze *whiter*; but the fact must not be overlooked, that from its tendency ever to precipitate lead in its combinations, *crazing* will readily ensue. The green tint is often improved by it, when sulphate of copper is employed. It has also another use, (and some persons substitute either manganese, or nitre,) to counteract the yellowish tinge often caused by the carbon of the fuel, without producing opacity of the glaze; the volatilization of the arsenic, by dissipating the gas of the carbonic acid, leaves the glaze not cloudy, but white, clear, or transparent.

Many of the less valuable kinds of flint ware are coloured by some additions to the materials for the glaze, forming what are called *dips*, *smears*, and *washes*. *Black dips*.—Blue clay 46 or 84, ochre 46 or 12, manganese 8 or 4. Mix in water, and pass through 12 lawn.

Black shining glaze.—Flinted slip 60, red lead 40 to 86, add manganese 14; or, flint 10, white lead 66, manganese 20, iron scales or sparks 4. Grind.

Brown dips.—Ochre 13, manganese 7, turner's shavings in slip 24 ounces, to pint 80.

Manufactures.

Or, calcined nickel 8, ochre 23, brick clay 23, Bradwell wood clay 23, brown clay 23.
 (Mingled.)—Or, shavings slip 75, calcined iron sparks 25, pass through 12 lawn, or yellow clay 97, zaffres 3.
 (Dark.)—Or, brown dip 80 or 48, slate clay (iron stone) 20 or 6, manganese 46.
 Or, brown dip 56, flinted slip 34, ochre 8, manganese 2, (or 4,) and Spanish brown 4, for porcelain.
 Red dip.—Brick clay 60, Bradwell wood clay 40.
 Brown glazes.—No. 1, raw glaze 33, No. 5, fritt glaze 67. For necks of jugs 67, and 33, (reversed.)
 Or, best flinted slip 33, flint 5, red lead 62. (For black, add manganese 2.)
 Blue dips.—Blue clay 28, petuntse 50, calcined gypsum 20, blue calc 2.
 Or, blue clay 26, Cornish stone 50, calcined gypsum 20, blue calc 4.
 Or, blue clay 38, petuntse 54, calcined gypsum 0, blue calc 8.
 Or, brown clay 23, China clay 15, flint 27, Cornish stone 27, blue calc 8.
 Grey dips.—Best flinted slip 75, flint 15, emery 6, manganese 4. Grind well.
 Or, best shavings slip 24 ounces to pint, 94, zaffres 6.
 Green dips.—Best flinted slip 96, copper calc 1, zaffres 3, (for sponge,) cane dip 96, zaffres 4.
 Or, calcined blue clay 75, zaffres 25, calc 20, best flinted slip 80.
 Or, (dark) stone body slip 94, zaffres 6, (olive,) black marl slip 92, zaffres 8.

Green glazes. Fritt.—Lead 54, flint 27, blue clay 9, copper calc 9, blue calc 1, raw glaze (2) 85, fritt 15.
 Or, Fritt.—Lead 33, copper calc 28, flint glass 17, flint 22, printing glaze (4) 80, fritt 20.
 Or, (for desserts) glaze 76, fritt 24; (for edging) glaze 60, fritt 40.
 Or, glaze (7) 1 gallon, biscuit yellow 12 pound, copper calc 8 ounces.
 Orange dip.—Brown dip 50, black marl slip 50. Cane dip.—Orange dip 50, best slip 50.
 Yellow glazes.—Raw cream colour glaze (2) 72, litharge 14, base yellow 14, or B. P. glaze (4) 80, biscuit yellow 20.
 Smears.—In hot water dissolve pearl ashes 60, nitre 16, rock salt 24, glaze (2) 80, solution 20.
 Or, in hot water dissolve pearl ashes 45, nitre 22, rock salt 33, glaze 86, solution 14.
 Or, in hot water dissolve pearl ashes 9, nitre 32, rock salt 59. For printing glazes.
 Or, in hot water dissolve pearl ashes 48, nitre 18, rock salt 34. For printing glazes.
 Or, in hot water dissolve pearl ashes 42, nitre 4, rock salt 27, soda 27. For printing glazes.
 Glaze for brown lined ware.—White lead 50, Cornish stone 40, flint 8, glass 1, borax 1.
 Blue and green. Edged.—Litharge 44, Cornish stone 24, flint 12, glass 12, fritt 8.

Fritt bodies.

(644.) Fritt Bodies. Porcelain.
 Fritt.—Cornish stone 40, bone ash 40, flint glass 20.
 Body: fritt 80, blue clay 20.
 Fritt.—Cornish stone 50, bone ash 50. Body: fritt 95, blue clay 20, flint 5.
 Fritt.—Cornish stone 40, bone ash 29, cullett 22, borax 9. Body: fritt 48, China clay 38, British clay 14.
 Fritt.—Cornish stone 22, flint 28, cullett 28, white lead 12, salt 3, borax 6, British calc 1. Body: fritt 40, China clay 48, blue clay 12.
 Fritt.—Kaolin 75, borax 20, sal ammoniac 5. Body: fritt 50, China clay 30, blue clay 10, flint 10.

Fritt.—Kaolin 60, borax 25, sal ammoniac 10, nitre 5.
 Body: fritt 45, China clay 40, flint 5, blue clay 5.
 Fritt Glazes, Porcelain, or best Flint, Blue Printing, and Enamel.
 Fritt.—Cornish stone 44, flint glass 30, flint 18, borax 4, nitre 4. Glaze for porcelain. (2) Body: fritt 44, cream-colour glaze (2) 56. Blue printing: fritt 78, lead 22, or 70 and 30.
 Fritt.—Flint glass 75, red lead 15, arsenic 3, nitre 7. Glaze: fritt 80, white lead 20.
 Fritt.—Cornish stone 31, flint glass 38, borax 31. Glaze: fritt 80, white lead 20.

Manufactures. *Fritt.*—Cornish stone 80, soda 20. *Glaze:* fritt 40, Cornish stone 20, flint 15, white lead 25.

Fritt.—Flint glass 76, red lead 7, potass 7, arsenic 4, nitre 6, also flint glass 47, potass 53. Mix fritts. *Glaze:* fritt 80, lead 20.

Fritt.—Cornish stone 24 and 13, flint glass 48 and 73, red lead 20 and 9, nitre 1½ and 4, flint 5, arsenic ½. *Glaze:* Cornish stone 30, fritt 36, flint glass 26, white lead 5, potass 3.

Fritt.—Petuntse 70, carbonate barytes 7, carbonate lime 10, boracic acid 12. *Glaze* for printing: fritt 64,

or boracic acid 26, nitre 5, potass 5; for enamelling, fritt 58 or 62, boracic acid 39 or 38, and nitre 3 or 0. **Mechanical Processes.**

Fritt.—Petuntse 60, calcined borax 34, nitre 4, soda 2. *Glaze:* fritt 60, borax 40.

Fritt.—Petuntse 60, borax 24, carbonate barytes 6, nitre 3, potass 3, salt 4. *Glaze:* fritt 62, boracic acid 32, nitre 6.

Fritt.—Petuntse 52, borax 36, China clay 3, nitre 7, soda 2. *Glaze:* boracic acid 40, fritt 60.

Fritt jasper bodies.—The materials to be ground together in slip.

Fritt.—Cornish stone 40, 50, 35, 40, gypsum 30, 50, 26, 40, flint glass 24, 24, 12, 12, flint 0, 16, 6, 6. *Body:* barytes sulphate 32, 32, 30, 34, China clay 18, 37, 30, 30, blue clay 18, 13, 10, 6, fritt 32, 50, 32, 30.

Fritt pearl bodies.—Grind all together in slip.

Fritt.—Flint glass 76, 62, 80, 70, red lead 22, 20, 20, 24, borax 2, 4, 0, 0, nitre 0, 8, 0, 6, flint 0, 6, 0, 0, *Body:* fritt 12, 16, 12, 20, 16, blue clay 38, 24, 28, 26, 30, Cornish stone 50, 46, 60, 0, 54, kaolin 0, 0, 0, 54, 0.

Porous bodies.—Marl 88, 84, 84, 86, blue clay 9, 10, 8, 8, flint 3, 6, 8, 6.

Cottage brown.—Bradwell clay 80, 60, 70, brick clay 14, 24, 20, flint 6, 16, 10.

Best red body.—Bradwell clay 25, 30, 40, brick clay 50, 30, 40, flint 20, 22, 10, blue clay 5, 18, 10.

The baking process will give a varied tint, from the place in the oven.

Processes and Manipulations.

Processes and manipulations. (645.) The first processes are immediately connected with the preparation of the *body*; in the language of the workman, the *clay*.

The *clay* for the body of the Oriental porcelain is prepared by a very laborious method. In paved tanks or pits, of some extent, men tread together the component earths, (much like treading plasterer's mortar in England,) until the mass is tawed or kneaded to a proper consistence; and during this very important process for securing fine ware, the workmen reject every particle of heterogeneous substances which they observe, whether introduced by accident, or by the adulteration of the cakes of mineral by the miners; because, it has been proved that hair, sand, or air bubble, will spoil the article in which it occurs. Portions of the well-trodden

mass are then manually rolled various ways on slabs, to render it homogeneous, and adapt it for the subsequent manipulations. (Wedging and slapping clay are kindred processes.) The *glaze* is prepared by more operose processes. The impalpable powders of petuntse and she-kao, (calcined gypsum, plaster of Paris,) are in proportions mixed in water; (by the workmen every liquid is named an *oil*;) calcined carbonate of lime is slacked by sprinkled water, and its powder, placed on alternate layers of fern, is repeatedly burned; and one per cent. of she-kao (calcined gypsum) is added to this in a suitable quantity of water. The two liquids (or *oils*) are next mixed, when of equal density, in the proportions of 90 of the former with 10 of the latter.

How little have those professed Chemists consulted their own credit who have literally copied the worthy Jesuit, Father D'Entrecolles's accounts without reflecting on their special import. The repeated calcination renders the lime more caustic, increases the dose of potass, and better adapts the glaze, not only of itself to fuse, but more effectively and readily to bring into fusion the surface of the ware on which it is laid.

Of the processes for the Dresden ware, we only know with certainty, that the clay is mixed with rain water at the equinoxes, when of a certain temperature, and when it is conjectured to be less adulterated with adventitious matters; and the ware is baked with only well-dried white wood, whose alkali, combining with that of one of the components, promotes vitrification.

The materials for coarse pottery are prepared by a very rude and ancient method. The place is technically named a *sun pan*. A level plot of land is enclosed by banks, and the inside of the boundaries is lined with planks or bricks; the bottom is formed of the ground. Upon this is scattered a small quantity of fine water-washed sand. At one corner is a square hole of about two feet and three feet deep, the sides of which are also lined. Into this the materials are cast and covered with water; then

Manufactures.

a blunger (see Art. 648.) is forced down, and the mass is very violently agitated to loosen the pyrites or gravel, that the larger particles may subside. When the mass has formed a semi-fluid, the workman lades it out with a small pail, and pours it through a hair sieve, which he agitates with one hand; and the particles which do not pass through are cast aside into the road. This is repeated until the bottom of the sun pan is covered to the depth of four inches; and then, at intervals of from two to four days, as the evaporation has proceeded more rapidly or slowly, additional quantities are poured on till the mass is twelve or fifteen inches thick; when this has acquired the consistence of strong dough it is cut out and placed in a vault for use. This method, vague, uncertain, and at variance with all scientific accuracy, is likewise practised in some manufactories of flint ware; and, to a very ignorant man, who mixes barrowfuls, not seldom does the manufacturer trust for the quality of the clay which forms his ware.

Slip making.

(646.) *Slip making*.—In the preparation of the clay for best flint ware, porcelain, and the beautiful ornamental bodies, for the sun pans is substituted the *slip kiln*. The *slip house* is a long building, usually separate from all others, of one story height, with the tiles of the roof laid half-way asunder, the more readily to allow the escape of the steam and vapour. In some of the manufactories, however, it is placed in the cellar or ground-floor. Unless two kilns are requisite, one part of the building is wider than the other; and in this are placed on the ground, on one side, large flags, for the process called *wedging* the clay; and on the other, deep *blending* or *blunging* vats of ascertained contents, from four to seven feet by three to six, and from two to four feet in depth, and marked by a graduated scale, with the sides formed also of very strong flags placed edgewise, and firmly cemented and clamped with iron. In each is placed a pump, for purposes hereafter mentioned.

Slip kiln.

(647.) The *slip kiln* (shaped like a brewer's cooling back) is a long trough or evaporating vessel, formed of particular shaped fire-bricks, the length of which is fourteen, eighteen, or twenty-two inches, the breadth ten inches, and the thickness six, four, or two and a half, according to the purpose, and their contiguity to the fire mouths. These large bricks rest on ranges of single common fire-bricks, laid so as to form separate flues for the heat, the whole length of the trough; and the outer range is firmly laid, and brought up to form sides, from twelve to eighteen inches above the surface of the kiln bricks; and the breadth of which trough is from four to six feet, the length from twelve to twenty-four yards. To prevent soot or smoke affecting the mass while evaporating on the kiln, the fire-places or mouths are at one end, outside of the building, and separated by a wall from the kiln; and the flues are continued into the chimney at the other end. The bricks being slow conductors of heat, the evaporation is of course comparatively slow, and the heat is more gradually communicated to the semi-fluid mass.

The slip kilns for porcelain clay, and those for ornamental wares, are made by a thick coating of calcined gypsum or plaster of Paris being run upon the bricks and on the sides, and thus is produced a slow evaporation; but the additional expense of the kiln is regarded as trifling, compared to the advantages of the clay being rendered more uniformly consistent during the very slow evaporation to which it is exposed.

(648.) The *blunger* (or blender) is formed of ash plank, seven feet long, sawed bladewise; the upper end is eight inches broad and two thick; the top shaped to a round form, on which is firmly fixed a cross piece, or transverse handle; the other end is about six inches broad by one thick. Another *tool* is rather like a baker's peel, with a spade handle, and a large *wooden mallet* is also used in the slip house.

Mechanical Processes.
The blunger.

The necessity of separate preparatory places, slip house, &c., is a result of the varying recipes being different, in each manufactory, in quantity as well as materials. The manufacturers of Kingtching obtain their materials in readiness for washing and combining as clay; and those of France purchase theirs from establishments at Limoges; reducing considerably the working capital requisite, as the body and glaze, in both instances, are prepared on the spot where the earths are quarried. But, as previously mentioned, each manufacturer can vary his components at pleasure, as suggested by experience or inclination, when the body and glaze are prepared by himself, or on his own premises.

That the ware may be of a certain quality the manufacturer directs the precise quantity of each component, which the slip-maker carefully takes of each kind of clay first: these he casts into a certain quantity of water in the blending vat, whose dimensions are known. The blunger is next pushed along the bottom of the vat a few times to loosen the mass; afterwards, after pushing it along, the man rests its flat side against the edge of the vat nearest him, and by the cross handle with both hands he forcibly raises the blade end, and whatever it touches, up in the water, and continues this laborious process until the whole of the semi-fluid has the uniform consistence of thick cream, and the density of twenty-three ounces per imperial pint; this being attained by adding water or clay, as needful. Inattention to this, and also to the addition of equivalent components when the mass has been increased, has frequently caused great losses in the baking. By the levigation in this vat will be loosened all gravel or larger pyritous matters not abstracted where the clay is quarried; these settle at the bottom, while the more completely to abstract less ponderous particles, the semi-fluid is pumped out of the vat, into a silk lawn sieve, which allows only those particles which are in a state of proper comminution to pass through into another vat, also of determined capacity. Into this vat, also, is pumped the proper quantity of Cornish clay, or kaolin felspar; and also of ground flint, each thirty-two ounces per pint, lawned; the blending is resumed, and the whole is pumped out and passes through the finest lawn, and in this intimate state of intermixture, free from all grosser particles, the semi-fluid runs upon the *slip kiln*.

(649.) *Clay-mill*.—The application of Machinery to this process has been successfully made in several of the manufactories where the power of a steam engine was at command. The *clay mill* (pl. xlviii. fig. 1) is formed of two strong cast metal parts of a conical figure, four feet high, and twenty-eight inches diameter at the wide end, and eighteen at the narrow end. These are firmly screwed together by flanches at the edges A A, and are placed with the narrow end downwards, firmly closed with a strong bottom, on which rests a brass step, and having in the side an aperture, like a parallelopiped, about eight inches by six. In this metal section, at certain dis-

Clay-mill.
Pl. xlviii.
Fig. 1.

Manufactures. tances, determined by the curve lines of a spiral, are screwed very strong blades C C, of varied lengths to reach near the centre, half an inch thick on the back, about one and a half broad on the blade, inclining to an edge, and tapering to a point. This is the passive part of the Machine. In the step on the bottom revolves the active part, which is turning an upright or vertical shaft E, moved by a spur wheel, in a collar step near the top. In this shaft are screwed, at right angles, similar blades D D, which radiate near to the sides of the cone, but arranged with such parallelism to the others as to traverse the space immediately near them, and act with the effect of shears on whatever substances intervene; but their flat sides form the lines of a spiral, and agreeably to its form and force, by every succeeding revolution, they cut the substances very small, and press them out at the aperture.

The flints are subjected to different processes. The nodules are calcined in a small kiln, resembling in form that used for lime, and while hot they are broken into small pieces by the miller, and then cast into the flint pan. Where mechanical power is available, the breaking of the nodules is effected differently. The object is to unite weight with percussion, on the principle of the pile engine, the accelerated fall of a heavy loaded beam. About two feet from the ground is firmly fixed a very strong iron grate, on which are thrown the flint nodules while incandescent. Above this grate are properly ranged, vertically, three stampers or wood beams, twelve feet long, six inches square, the lower end strongly shod with iron, and the upper has a projection or strong catch pin resembling a stamping-mill. (Art. 225.) The line shaft is supported by a step in the wall of the mill; and on the end is a walloper wheel, provided with three wipers or crank-like projections, about eighteen inches or two feet diameter, that catch and raise the stampers in succession; and these, when left free by the rotation, fall with great force and break the flints small, and the fragments fall through the grate and are thrown into the flint pan.

Flint pan. (650.) The *flint pan* consists of a circular vat firmly hooped together, and from eight to ten feet diameter, and twenty-four to thirty-six inches in depth. The bottom of this vat is paved with small blocks of hornstone, quartz, or felspar, as preferred, laid firmly in some mortar of the material to be ground. In the centre moves an upright shaft, on the upper or lower end of which is fixed the spur wheel; and a strong firmly fixed hoop or barrel, about fourteen inches high, surrounds it inside the vat, to prevent injury to the materials. At right angles to this shaft are four very strong arms and grating framework, on the bottom of which is a ledge, and round which is a slug-iron, to bear the *runners*, very large blocks of the same substance as the *pavers*. Water is put in to the depth of eight inches, and the broken pieces, flints, Cornish stone, or felspar, are thrown in, and the whole being put in motion are abraded against each other, and the pavers and runners, in the water, till they are reduced to very fine particles, and the fluid has the consistence of thick cream, with a density of thirty-two ounces per imperial pint. The constant forcing of the whole mass in contact with the hard stones abrades also a portion of these latter, and the manufacturer has to calculate on the presence of this heterogeneous substance in his mixing. One ton of good nodules should grind into one hundred and twenty pecks of flint pulp.

Mechanical Processes. The selection of pavers and runners demands considerable attention. Whether grinding flint, Cornish granite, bone, felspar, or glaze mixtures, there will be some minute portions abraded, which to a certain extent affect the pulp. During many years the Derbyshire hornstone (technically named *chert*) was used; but ignorance on the part of the millers caused some to be employed, in which carbonate of lime was present in extra proportion, and its mixture with the flint rendering the flint ware fusible at a heat lower than usual, several ovens full of ware were fused down before the error was discovered. Other instances were ascertained of the pavers being calcined among the flints, and ground therewith, in consequence of which the ware *rifled*, and the law had to determine which party should bear the losses. The chert of the Halkin Hill was found very excellent, and is now preferred; but however free from lime, as it abrades, though less than flint, in 1832 pavers and runners of granular quartz were introduced in many flint-mills; and in 1834, the green felspar or kaolin, previously calcined, was first used for grinding materials for porcelain bodies; and the fawn-coloured, or white Middletown Hill, previously calcined, for best glazes.

The Cornish granite for body and glaze, or petuntse, is ground to the weight of thirty-two ounces per pint; the felspar for body, to the same weight; but for glaze to twenty-eight ounces. The glazes vary with the nature of their components, and are adjusted in the hand glaze-mill.

When the flint nodules are reduced to a pulpy state, the semi-fluid, is poured into a *washing pan*; a smaller vat, with a lighter shaft and radiating framework, and small arms similar to a capstan, by which the pulp is agitated violently in an additional quantity of water, which carries away any soluble salt of iron, and also allows the more weighty particles of the clay to subside, to be again thrown on the mill. The fine pulp is then poured into additional water in an ark, one of the sides perforated with holes for plugs, which can be in succession drawn as the pulp increases in density, and the water also carries away another portion of iron. Cornish granite and Middletown Hill felspars are similarly washed; and when the former is dried on a kiln, much like the slip kiln, it is technically named *composition*. The felspars are similarly dried.

(651.) *Blending-mill.*—The small lumps of clay from the clay-mill are cast into the *mixing* or *blending-mill*; (fig. 2;) a circular vat, D, about seven feet in diameter, and three feet deep, within which moves a vertical shaft A, that has four arms of wooden framework B B B B, radiating at right angles, and which resemble strong gates; these, when put in motion by the wheel E, violently agitate the whole, so that while the denser particles gradually sink till they are lowest in the semi-fluid, the finer particles remain suspended, and are yet more intimately intermixed, by being passed, with the proper quantity of flint, through successive lawn sieves of increasing fineness, at the end of each spout, agitated by cranks and belts, and then conveyed upon the slip kiln.

On the slip kiln the semi-fluid is subjected to continued heat, which causes constant ebullition, until the surplus water is slowly dissipated in steam and vapour. Attention is paid by the slip-maker to keep the semi-fluid in agitation during the early part of the process,

Blending-mill.
Fig. 2.

Manufactures.

that the greater specific weight of the flint may not be allowed to operate in its subsiding, and thus be found plus in one portion of the clay, and minus in another, of the same making; also, to prevent the mass next the bottom becoming hard and the upper more fluid, by the expulsion of the moisture, and the subsidence of the particles, as well as because of the reciprocal tendencies of silica and alumine, which, when humid, readily assume the consistence of mortar, that speedily hardens, and in a short time assumes a solidity which the subsequent action of the atmosphere does not easily affect or decompose. When the cessation of air-bubbles on the surface, and the homogeneous appearance of portions cut out of different parts of the mass on the kiln, lead the slip-maker to consider it as adequately evaporated, and of the consistence of strong dough, and sufficiently hard, yet not too hard, to properly yield to the hand of the thrower in his manipulations, or of the presser's beater in preparing it for the moulds, the fire is abated, and the mass is quickly removed into the other part of the slip house, where it is subjected to the process of *wedging*.

The process of blending appears to need simplifying on some regular plan. The laws of chemical combination determine the reciprocal tendencies of substances; and these being known, as well as the proper density of their mixtures, whether clays, flint, Cornish granite, or felspar, it seems requisite that the density of the clay mass or body should also be determined; in which case there might be a ready way for mixing, by putting into a gauged vat a certain quantity of water, and a specified weight of each material component; the mixing-mill would of course beat the whole together, and if allowed to run over into spouts and lawns the final lodgement would be on the slip kiln. The reduction in volume of certain substances in combination precludes all certainty of calculations, so that these can only be verified by comparison. There is a certain rule for determining their specific gravity, which may be thus briefly stated. The specific gravity of bodies is as their weights divided by their volumes; and the mean specific gravity is the quotient of the sum of the weights divided by the sum of the volumes. Make the two weights W, w , the two volumes V, v , the two specific gravities P, p , and the calculated mean specific gravity M ; then

$$M = \frac{W + w}{V + v} \text{ and } V + v = \frac{W}{P} + \frac{w}{p} = \frac{Wp + wP}{Pp};$$

$$\text{hence } \frac{W + w}{V + v} = \frac{W + w}{\frac{Wp + wP}{Pp}} = \frac{(W + w) Pp}{Pw + pW} = M.$$

The slip-maker may most carefully observe his instructions, and also the several components be in strict accordance with the principles of mixing, likewise in precise proportions, and yet the clay be deficient in the adhesiveness indispensable for the workman to use with the greatest advantage to the manufacturer, and with only the usual trouble to himself; frequently the presser, to his great inconvenience, found that the *clay bat* would not hold together sufficient time to be lifted from the beating slab to the bench and mould. No remedy for such a disaster is suggested by the chemistry of atoms; and the chemistry of masses has not been regarded with minuteness adequate to present theory for the cause and effect; consequently practice only was left for explanation, and experience teaches most efficiently. The workman had frequently noticed

that the clay in which was mixed with the fresh components some quantity of *old* clay, (or which had been used by the thrower and cut off by the turner,) produced a greater quantity of sound ware than clay made wholly of fresh materials; and, on the supposition that a body which had been once worked would more readily amalgamate with the fresh material than with all of the latter only, the introduction of a certain quantity of turner's shavings into the blunging vat verified the supposition; and thus the surplus clay on the vessels becomes a second time available, and renders the mass adhesive for any manipulation. The practice was particularly requisite when the Middletown Hill felspars were first introduced. The components were carefully mixed and made into clay by the slip-maker; which clay the thrower formed into strong thick vessels, and left them to the requisite evaporation, and the green state, the reciprocal chemical action of the components in giving up their water; the turner next cut the vessels completely away in thin shavings, which were again carefully added to a certain quantity of fresh materials previously blunged and lawned by the slip-maker; and of these was formed clay for the best porcelain, which was suitable for the workman's purposes. In the preparation of the clay for the Sevres porcelain, however, there is found a necessity to add a certain proportion of baked ware, again ground into an almost impalpable powder; and in deficiency of this, the materials are formed into thin stilts, baked well, and ground; and only after these processes can the clay be worked. The reason of this intermixture is given under the directions for making seggars, and in the statement of properties essential to the body of chemical utensils. The person who first introduced these felspars, and who thus was the first to supersede the use of the noxious and most deleterious article *lead* in pottery glazes, was James Ryan, F.S.A. who suggested the following process as adequate to the purposes of the additional biscuit materials of Sevre ware:—Let the large blocks of felspar be well calcined by wood, turf, or fern in a kiln like a limekiln; and use these blocks as *pavers* and *runners* in the mill which grinds the felspar; and as all the contents of the vat will then be of the same kind of materials, the small portion abraded off the calcined blocks in grinding the other will be found usually equivalent to the baked component, and when any biscuit pieces are not saleable, they need only to be cast again into the vat, in certain proportions with the fresh felspar, and again they are useful, instead of being cast on the heap of potsherds.

(652.) *Wedging* is the next process; and is, in the published descriptions, confounded with *slapping* the clay for the thrower, or by the presser. When the clay is properly evaporated, it is carried from the slip kiln and laid on the flags above described; but as it then contains a great number of air-bubbles, these, although very minute, must, in the manipulations, be burst and destroyed, because, were they left in the clay, the air they contain would be so rarefied during the baking of the ware as to expand that portion of the vessel; and when the bubble burst, either a blister or a crack would ensue, either of which would depreciate, if it did not completely spoil, the ware. To accomplish this effectually, instead of *treading* the mass like mortar, as is practised by the Chinese, a mallet is used to beat it together, and so prepare it for being cut into small pieces by the spade-like tool described Art. 648. From different parts of the mass, the person in succession cuts off a small piece, which he

Mechanical Processes.

Manufac-
tures.

forcibly casts down, and repeats this laborious process till all is formed into a heap, thereby admitting the action of the atmosphere on the small portions to mellow each by thorough cooling, and also bringing the whole into one state of equal density, so that, wherever it is cut, the intersected portions will present a smooth homogeneous appearance.

Where there is steam power, a mill, like that used to break the crude clay, only with rather broader blades, is employed to supersede the manual labour of *wedging*. This mill not only performs the cutting equal to the parting it by the tool, but also the beating with the mallet, and the wedging it by casting on the heap. The repeated separation of the mass by the revolving blades destroys all the air-bubbles; and the constantly increasing pressure from their spiral arrangement, in the contracted space, gradually solidifies the mass, and renders it more and more compact, until, in one homogeneous mass, it is forced through the aperture, resting on rollers on a table, and an attendant, employed in some manual process, cuts it into brick-shaped lengths of about half a hundred weight, and places each in a vault until the workman needs it.

All pressure and mechanical means adopted are found, however, incapable of effecting that intimate combination which results from the mass lying some time before it is used. After the clay therefore has been wedged, it is placed in the vault to remain as long as the conveniences of room, capital, and time will allow, before it is employed in the fabrication of vessels; and the longer period it remains, the better is it adapted for the purposes alike of the workman and the manufacturer. We have heard that Wedgwood's jasper body lies never less than six months; yet, many persons, though fully aware of the advantages of delay, preferring an immediate turn of capital to a greater but more remote benefit, if they do not resolutely oppose the practice, or have not capital to keep up a large stock, may have ware manufactured of clay taken into the work rooms reeking hot from the slip kiln, and after an interval of only a few hours from its being in ebullition. Can there be any wonder that great losses in the baking are consequently incurred?

At Etruria by Mr. Wedgwood, first, and at Stoke by Mr. Spode, next, the power of the steam engine was applied to break the calcined flint nodules by stampers; to grind them in water, to cut the crude clays, and mix the components in blending; to move the lawn sieves as the semi-fluid passed to the slip kiln; to cut, mellow, and wedge the evaporated clay, and to drive the wheels of the thrower and turner.

Slapping.—The clay used by the thrower is placed on a strong bench, and a man with a brass wire cuts off a piece many pounds weight, which he lifts up, and with all his force violently slaps it down on the mass; and this is frequently repeated until it is apportioned by the *baller*.

Throwing
of porcelain
and pottery
Fig. 3, 4.

(653.) *Throwing of porcelain and pottery.*—The *thrower's engine* or wheel (fig. 3) is a box-shaped frame D, fitted into one corner of the room, about a yard in diameter, and with a curved front. In this is fixed, in a firm frame, a spindle or axis B, working vertically in a collar C and step E. Near the step is fixed on this spindle a multiplying wheel, with the pulleys of different diameters for changing the speed, as the vessels made are more or less heavy. The top of this spindle has the head A firmly fixed thereon, and around is the space for the

Mechanical
Processes.

workman's feet on each side; in the corner is a seat for him, and the front allows full scope for supplying the clay and taking off the formed vessels. At the distance of four or five feet near the ground is a guide pulley F, under which passes the driving cord to the rim of the large wheel G, at four or five yards' distance, and to which, by a winch on its axis, motion is readily given by a proper person.

Where steam power is available, we find two cone drums (fig. 4) placed inversely, on parallel shafts A A, employed to give motion to the thrower's engine, for forming those large vessels in which manual labour would be expended to great disadvantage. The main shaft, or horizontal spur gearing, has a fixed bevel wheel which works in and moves another bevel wheel B on the top of one of the vertical shafts; and at the bottom of the other vertical shaft are two pulleys for a belt, one firmly fixed to communicate motion to the thrower's engine, the other loose, for the belt to remain on during the cessation of motion. On these two shafts the cone drums, of exactly the same dimensions, are fixed, with the apex of the driving drum opposite the base of the other. This relative position allows a broad leather belt D to traverse the whole extent from either extremity to the other, and yet be always tight; only the motion of the driving cone, when the belt is near to its base, giving the maximum velocity to the other, whose apex it traverses; and this velocity diminishes as the belt ascends to the apex of the driving cone, on which it is at its minimum; the thrower's engine accordingly has varied velocity at pleasure, by the position of the driving belt; this is effected by a simple contrivance of a directing lever, with a guiding loop-hole, which a boy with a winch moves, agreeably to the thrower's instructions, and by practice is so intimately acquainted with the manipulations, as easily to adapt the velocity to the work in progress, and when this is completed to the satisfaction of the workman, to direct the belt on the loose pulley and stop the Machine.

At a bench near the throwing engine stands the *baller*, usually a young woman, before whom is a large lump of clay. From this, with a brass wire, is cut small quantities, each of which is weighed, when the body is valuable, and the vessels must be of a determined size; this is then well slapped between the hands to expel water and air-bubbles, and formed into a ball, which is placed nigh the man, or put into his hand, as the ball is small or large in size.

On the seat in the corner of the frame already mentioned, the man places himself, with one foot on each side of the wheel head, and his knees supplying rests for his elbows, when his arms require to be very steady. The great numbers of vessels of the like dimensions and shape constantly requisite to be formed, (and which we scarcely need mention must necessarily be of a *circular* kind,) is ensured by the man placing his gauge, a peg or stick, in a lump of clay, at a certain distance from the centre, to indicate whenever the plastic figure coincides in the requisite height and diameter, and the vessel has attained the proper dimensions.

The thrower directs the person at the large wheel, by the word *turn*, to the velocity he requires. He then very forcibly casts on the wheel head a ball of clay, which with both hands, previously wet, and at intervals dipped into water near him, he repeatedly squeezes up into a high conical column, which he forces down again into a lump, until there is little probability that any air

Manufac-
tures.

bubbles can remain in the mass. With one hand, or finger and thumb, *in* the mass, and the other on the *outside*, or with his fingers only, he gives the first rude form to the vessel, and by a swage, rib, or other utensil, that has the profile of the shape of the vessel, smooths the inside, gives the proper shape, and removes the *slurry*, or the inequalities left by his fingers, until it is completed to his satisfaction. With a piece of fine brass wire, with a handle at each end, he quickly cuts off at the base the vessel thus roughly formed; the baller hands him another ball, and with great facility lifts off the vessel, and places it on a board, on which it remains (occasionally turned upside down) until all on the board dry gradually to a certain consistence, which is called the *green state*, because it is that when, more than at any other, the clay possesses tenacity and firmness to bear without injury the subsequent manipulations; it being only when in this state of complete chemical reaction of the silicic acid, alumine, and water, that turning, smoothing, fixing the handles, spouts, ornaments, and other appendages, can be effected.

Jigger
described.

(654.) The *jigger* also, called a *throw* by Mechanics, is larger than, yet much resembling, a lapidary's wheel, having a vertical spindle, with a winch, pulley, and belt fixed to work in a bench, and a block to fix firmly on the top of the spindle; this is used to give motion to plaster moulds placed on the block, while making circular dishes, plates, saucers, shallow bowls, and many other vessels, and also many oval *hollow-ware* articles. In some manufactories, the throwing engine is employed for this purpose.

A considerable number of pieces of clay, of a determined size and weight, are batted for the purpose, (see Art. 659.) corresponding to the number of moulds at liberty. A mould is placed on the head of the throwing engine, (or on the block on the top of the jigger,) and motion being communicated, on it is laid one of the bats of clay, which the workman's hand presses close to the mould, and thus gives its interior shape; next, as the motion continues, its exact figure and thickness are regulated by a swage or profile and wet sponge; and, when a ledge is required, a thin strip of clay is laid on with slip; (and any feet are added, as described under *handling*;) all extraneous matter is cut away, and a horn tool and damp sponge are used to finish the article. The moulds are placed in regular succession in a stove, and when properly dry, the bats are taken off, the edges are carefully pared, the last polish is given by slightly passing the hand over the pieces, and in *bungs* (piles) of more or fewer, as heavy or light, they remain in a drying place, until they are ready for being placed in the seggars to be baked biscuit.

Turning.

(655.) *Turning*.—This manipulation requires considerable dexterity in the workman, to avoid destroying or fracturing the vessels, while forming them to their requisite size, thickness, and correct shape of circular vessels; and it presents numerous opportunities for the exercise of skill, taste, and genius, in giving to the several parts the rings and rims required, and to the whole all the elegance suggested by the pattern, and the little niceties, either with much difficulty, or by no effort, obtainable when on the throwing engine.

The *turner's lathe* has much resemblance to that used by wood turners; but the spindle is longer, the crank on the wheel axle describes a larger circle, and the treadle is differently formed, with a cross piece, that the treader may with more ease produce, and,

as proper, regulate the motion required by the vessels, while the turner stands steady in performing his manipulations. On the crank axle, below the cheeks of the lathe, is fixed a rather heavy wheel, about three feet diameter, and in its rim are three grooves for the cord to turn the spindle; a wainscot partition separates it from the space into which fall the turnings while the work is in progress. The end of the spindle outside the collar step and headstock is formed into a screw, to which are fitted a number of *choques*, each tapering gently, and in diameter adapted to easily fit the inner surface of the vessels which need turning. Near the headstock is a small shelf, on which the treader keeps a supply of vessels, to prevent delay to the turner.

Mechanical
Processes.

The *engine lathes* are constructed with the collar step, readily movable horizontally by a spring, between two check screws, and with a catch pulley (varied in size for the incision of the plate) fixed at pleasure; against this strikes a circular iron plate called a *movement* fixed on the spindle, and in whose edge incisions of more or less extent are formed at certain distances, so as to give to the spindle slight horizontal and vertical motion during the rotary motion caused by the wheel.

At the Etruria manufactory, and at one at Stoke upon Trent, belonging to Copeland and Garrett, are rooms in which the lathes are placed in rows, and the motion is derived from the steam engine at each. Near the ceiling and one wall of the room runs horizontally a general driving shaft, on which are fixed the same number of small drums, about eighteen inches long and two feet diameter, as there are lathes, and from each drum is a belt to the fixed pulley on a small shaft below, placed lineally with the spindle of the lathe. This shaft has also two loose pulleys with sliding collars and catch gearing, to be at pleasure set in motion by the fixed pulley. From the pulley a cross belt passes to a pulley fixed on the spindle. The pulley is of three sizes, corresponding with another pulley counter-placed on the spindle, so that the belt fits wherever it may be guided by the turner, to increase or diminish the velocity of the spindle as he is proceeding with his labours. When these are perfected as far as the *turning* is requisite, the pulley is thrown out of the gear, and the other with the cross belt is set in, and gives to the spindle retrograde motion, by which the vessel is smoothed, solidified, and polished, as subsequently explained.

The turner's tools are of iron, thin and well forged, usually about eight inches long, with a sharp part to fit into a handle when worn very short. Their breadths differ from a quarter of an inch to two inches, and the cutting end is turned up at a right angle about half an inch, and then on the grindstone, or by a file, the inner edge of the turned-up part is made sharp and truly level.

A little raised above the treadle by a block or seggar, stands the treader, at the end of the spindle, so as to have entire command of the lathe cord, and be able easily by mere pressure down of the treadle by the foot to give adequate motion to the spindle and the vessel on the *choque*. Near the treader is a board bearing the vessels which require turning, and as the workman is employed in his manipulations, the treader is also further employed in moistening the upper edge of the vessel, and clearing away whatever may risk its turning, or delay the operation; and on this being done each vessel is placed on the small shelf already mentioned.

Manufac-
tures.

The position of the turner while employed on earthen ware is the reverse of that of the wood turner; for instead of standing exactly linear with his lathe, or aslant a little from the headstock, he looks towards this, and remains at entire freedom from every thing which might render him unsteady. On the choque is a clay ring, kept scarcely moist. The vessel to be turned is put on the choque, and as soon as the treader gives motion to the spindle, the turner presses with his tool or finger the upper edge, already moistened, into the clay ring. Next placing his tool opposite the transverse axe of the piece, he carefully cuts away all surplus clay left by the thrower, and reduces it to the precise thickness required; (in very valuable articles the turner weighs each vessel.) The ornamental portions are formed, and, when engaged in *engine turning*, while the spindle is in slow motion, the back spring causes the incisions of the circular plate or movement to bring the vessel nearer to the tool, and those parts are in consequence cut away in diamonds, dice, or other fanciful indenting; and the full part carries it away again, so as to form these dice, &c. at distinct distances all round the vessel. When all the *cutting away* of the clay has been completed, the treader very expertly gives to the spindle a retrograde motion, during which the turner applies the flat surface of a broad tool on the upper part of the vessel, and by gentle pressure thereon gives to the whole vessel a solidity not previously existing, and a glossy smoothness of surface, removing all inequalities left by the prior manipulations. The vessel is next cut loose from the clay ring and placed on a board for the handler, or to dry for the biscuit oven.

Handling
and figur-
ing.

(656.) *Handling and figuring*.—These manipulations fix on the clay vessels their handles, snips, spouts, ornamental figures and foliage, and whatever other required additions are to be made after the manipulations of throwing and turning. For the best sort of vessels these are first formed in moulds, (Art. 659.) of which an adequate number are in the charge of the handler, and kept placed around the stove, that they may prepare another succession of the articles while he is affixing in their proper places on the vessels those previously abstracted.

Fig. 5.

But for readily forming the handles for less valuable vessels, jugs, &c., recourse is had to a small Machine called the *squeezing box*, fig. 5. An iron cylinder A, six inches in diameter and twelve inches deep, with a very strong bottom, whose centre has an aperture about one and a half inch diameter, is firmly fixed in some place, conveniently high, and of ready access without disturbing any other arrangements. Screwed or riveted to the upper edge are two inch square iron bars, six inches long, on the top of which is screwed a cross piece B, the middle of which is very strong, and perforated with a female screw, in which the other cross piece C works, cut fine or coarse, as the process has to produce a very solid and fine article, or one of less value. On the upper end of C is fixed a transverse handle D, and the lower end works in a socket in the piston E, a plate of strong iron, turned to the exact size of the cylinder. In the aperture in the bottom can be inserted pieces of lead, in each of which is pierced the size and section of the handle, agreeably to the taste and desire of the manufacturer; and in this is fixed a steel pin, vertically, when tubes for the purposes of the chemist, or for ornamental tobacco pipes, are to be formed, but not necessarily so in all cases. The piston being screwed up above the

Mechanical
Processes.

box, a quantity of well slapped clay is put in, the piston is then screwed down on it, and when its force is fully exerted, a portion of the clay constantly exudes through the hole in the lead piece, and is received on a board the whole length; and thus are formed a number of strips of clay which are left to dry a short time; they are next cut into proper sizes, bent into the requisite shapes, and left to dry a little longer.

The handler prepares his spouts, snips, handles, &c. in regular succession, by cutting away (with a sharp knife of the kind used by cordwainers) from the edges or ends every little portion of superfluous clay. For placing on the handles, he cuts level a small space of the proper size on the curved surface of the vessel, and for the spouts, (as of tea or coffee-pots,) with a sharp-pointed knife he either cuts out an orifice, or forms a grate of the size and shape of the larger end of the spout; and for snips of jugs, &c. a piece is cut out of the upper edge of proper size and shape. He next moistens the edges of the orifices and articles to be affixed with slip, then, while they are moist, places them in contact, and they remain a few minutes undisturbed. Again they are inspected, and, when requisite, a little slip is added, and by gentle pressure with a proper tool they are brought properly together, whatever parts were not joined previously; but when found completely connected they are left till sufficiently dry to bear holding in the hands, as the knife is applied to trim off all excrescences. The vessel is rubbed over with a moist sponge, to take away any dust or adhering matter, and to moisten the whole equally, so that the appearance may be uniform, and no injury ensue, while gradually drying prior to being placed in the seggars. But in using the sponge in this manipulation considerable attention is indispensable, because not unfrequently has the sponge been so often applied, that much of the alumine has been taken away, and the silica left, to which the glaze would not adhere in glaze baking, and dry spots have been formed on the outer surface, rendering the vessels of little value.

The *figurer* is usually a workman of extra dexterity and some genius. He mostly has in his train a youth, to whom this is a preparatory lesson as a *presser*. Into moulds of plaster, (see Art. 659.) or, when great numbers of the subjects are required, of copper, always oiled, the more readily to *deliver* the relief, for convenience and facility, soft clay is pressed, to form the figures, foliage, animals, and other beautiful subjects, in relief, exhibited on vases for chimney mantels, &c., and on the more valuable kinds of jugs, tea-pots, and ewers. When these are rather dry their exposed surface is cut quite smooth with a sharp knife, and then polished; afterwards they are taken out of the mould, left a little to dry, and then moistened with slip, placed in proper positions on the vessels, allowed again to dry to bear trimming off, and then they are finished for baking.

Great attention and care is employed by the modellers and figure-makers in their imitations of the foliage and petals of plants in porcelain, each often requiring a separate mould; and occasionally this is inapplicable, and must be supplied by manual dexterity and ingenuity. To properly, and with more ease and facility, effect this, there is mixed with the clay some starch powder, or other mucilaginous substance, which renders it more adhesive while being worked, but increases its beautiful and porous appearance after being baked.

(657.) *Modelling, mould making, casting, and pressing*. Modelling.

Manufac-
tures.

—These manipulations have immediate connection with the forming of all vessels, jugs, beakers, &c., not circular, or not plain on the surfaces.

The *modeller*, having to supply *blocks* of all new patterns and original productions approved by the manufacturers, he forms, according to the intention, in clay the true image required; or when at liberty to indulge the exuberance of his fancy, with due regard to propriety, elegance, and accuracy, he executes in his best style the offspring of his genius, and with tools of steel, box, yew, and bone, carves, trims, touches up, and re-touches the various parts, until he has finished the whole in the state of perfection desired, or according to the adequateness of his remuneration. These are frequently works of considerable skill and art, and in their invention and production the proper portion of genius ought constantly to be exercised.

Gypsum, or native sulphate of lime, usually called *plaster of Paris*, supplies the material for the formation of the moulds. The crude rock is ground in a mill between a pair of stones resembling those of a corn-mill. It is afterwards placed on a small kiln or trough similar to the slip kiln, having flues beneath by which it can be heated; on this the whole is *boiled*, that is, the water of crystallization is dissipated, leaving the mass a soft, impalpable powder. The man who superintends the mill usually protects his mouth by a double silk handkerchief, to prevent any particles being inhaled or swallowed, by which his lungs would become charged and his stomach disordered, disasters very injurious, and which often have arisen to the careless. The plaster retains a powerful tendency to solidify quickly, but not to crystallize, when supplied with a certain quantity of water, which adapts it for being readily cast into moulds, as well as for being employed in the manufacture of various articles. Naturally absorbent of water, this property is further promoted by the moulds being kept at a high state of dryness on shelves around a stove in a small apartment; and whenever there is little tendency for the components of the body, (and even when there is much it is counteracted by a size, or the dust used by the presser,) the clay can be applied several times daily.

The *mould maker*, quite distinct from the modeller, is usually a man of considerable judgment, who has to form the plaster moulds, so that they will readily separate into parts for greater facility and correctness in producing the intended vessel or figure. He has to exercise much care in making those for the dish-maker and presser, but especially those for the *casting* of figures, &c. The block or model is placed on a board of proper size, and at the distance of the intended thickness of the mould is securely fixed a strong *cottle* or clay bat. A certain portion of the block or model is also covered with clay, and the exposed portion is covered with a coating of size made of 1 ounce of potash, 1½ ounce of soft soap, and 2 ounces of China clay, boiled slowly in a pint of water half an hour.

The workman then takes a certain quantity of water, (and for some particular moulds adds urine,) into which he puts by measure a proper quantity of plaster, which he quickly and briskly mixes together, and then pours the semi-fluid around and over the model until the upper part has the designed thickness. The combination of the plaster with the water evolves some heat, which increases during a few minutes, until the mass is sufficiently compact to bear removal; it remains a short time,

and the clay cottle is separated, and in succession are all the parts of the model covered, and those of the mould formed. In a few hours the whole becomes a compact bibulous mass, easily separable from the model, and presenting a correct *fac simile* of even its minutest lines and ornaments. The mould is next placed where it can dry very regularly, and soon is ready for use; and when put near a stove may be five or six times daily covered with fresh clay bats, and so absorb moisture from them that in a moderate time they are so dried as to be a little contracted in size, causing the vessel or figure to slip out (and the mould is said to *deliver*) easily, readily, and perfectly; fresh bats are put into the moulds, and while they are drying, those taken out are undergoing the requisite manipulations of trimming and finishing.

(658.) *Casting* is adopted to considerable extent in the manufactories at Derby, Sevres, and Tournay, where all tea ware is cast, and several hundred moulds are used together. Where much beauty, delicacy, and niceness, but little strength comparatively, are indispensable, and there is particular need or desire to obtain the fine sharp lines and perfection of ornamental articles, and elegant figures, busts, and vases, this is allowed to present the most ready and accurate method of accomplishing the object. All the parts of the moulds fit so close that the semi-fluid is altogether retained; but, of some figures, distinct series of moulds are used for the head, arms, legs, and trunk, all of which are carefully joined together with slip, and finished when properly dry. Wedgwood's productions are deservedly celebrated in this respect. The body is diluted in pure water to the consistence of thick cream, and this semi-fluid is poured into the cavity of the mould, where it remains a longer or shorter time, as deemed requisite. The plaster immediately absorbs the moisture of that portion of the mass contiguous to the mould, and it hardens so as to be fixed in a stiff coating attached to the mould when the portion of the fluid is either poured or by a syphon drawn out. In a short time a more dense mixture of the body is poured in, and left rather longer than the former before it is poured out. The mould and what it contains are placed on a board near the stove, until the contents are sufficiently deprived of moisture to support removal freely, and present an exterior surface precisely corresponding with the original figure. The subject is placed aside till in the *green* state, and then the workman removes all redundancies, remedies all imperfection, and for its full completion exerts his utmost skill. When rather dry it is brushed from dust and carefully rubbed smooth with tow.

(659.) *Pressing* (often called, technically, *hollow ware squeezing*), is another, and very laborious, manipulation. On a bench are fixed some rings or cottles of clay, thick and strong, and into the space is poured a very dense mixture of plaster and water, which is left to combine several hours, (or days when convenient,) and after it is properly set, it is completely soaked in water to prevent the clay adhering to it, while being beaten or *batted*. The presser considers well the size of the mould he is to use, and the thickness of the articles to be formed. From a mass of clay before him, with a brass wire he cuts a piece of suitable size, which he repeatedly squeezes in his hands, forms into a ball, and forcibly casts down on the bench or board, to prevent any air-bubbles remaining in it. This he beats on the plaster block with a plaster batter, by an expertness and

Mechanical
Processes.

Casting.

Pressing
described.

Manufac-
tures.

dexterity only to be understood by being witnessed, and the requisite figure and thickness is thus given to a number of *bats*, for preventing the delay of forming each just when wanted to be put on the mould. After the bats have been prepared a short time the mould is placed on a whirler, the bat is put on it, and with a moist sponge is *bossed* (forced) into it; the different parts of the mouldings are similarly covered with a bat. When the mould is in one piece the thumbs are employed to work the clay very solid, and preclude its liability to crack, and to press it into the different ornamental parts and several corners. The great size and weight of the bats and moulds for large dishes render the manipulations so laborious, that a man and his assistant with great exertion can seldom make four per hour; neither do they continue their laborious employment the same number of hours as the other artisans. But some of the moulds have several parts, into each of which the clay is worked as above mentioned; the inner surface is rendered smooth with the moist sponge; with a sharp knife all extraneous masses are trimmed off the edges, and these are moistened with slip; all the parts of the mould are next put in proper connection together, and secured when requisite by a belt buckled round them. The finger is next drawn forcibly up every joint, into which afterwards is put a thin roll of clay, which is worked into the mass by the finger and thumb first, and next by a thick smooth leather, to render the clay smooth. With a sponge moistened with slip the wreathes or wales are expunged, and with another sponge moistened with clean water the inside is carefully washed; the mould is now to be placed a short time aside to dry a little, and again it is placed on the whirler and polished with a smooth thin plate of horn. The mould is next removed to a shelf near the stove, and there it remains until by absorption of the water and its evaporation the clay article will readily separate; and when in this state it is taken out and placed on a flag to harden a little, that it may be *fettled*, that is, by proper tooling and trimming, freed from all appearances of seams. All extra clay is cut away, the whole is rubbed with the wet hand first, then with the moist sponge, to clean it; the handles and other ornaments required are next placed carefully where proper, and the whole is polished with the horn, and placed to dry for baking.

In manufacturing porcelain, the articles, after being finished in the clay, are placed either on plaster flags ranged in the room to more gradually part with the remaining moisture; or on boards above the workman's head, or resting on props fixed in the walls, or ranged upon frames in small apartments solely appropriated and heated for the purpose, and committed to the care of the *looker to the ware*; a man on whose careful attention to the gradual rise of temperature from the last manipulation, until the several articles have the appearance in dryness and colour of the dried plaster of a new wall, depends the excellence of the ware; because the shape would alter, and the vessel probably become useless, did any part of it again become moist through a lowered temperature.

This subdivision of labour, by distributing the work among a great number of work-people, is proved advantageous in causing the whole to proceed rapidly with great regularity. Incessant attention to one operation solely, whatever it be, renders each artisan dexterous and ready in its performance, and no time is lost in changing implements; as when each man, to be called a good

workman, performed the distinct manipulations to *throw*, *turn*, and *stouk* (handle), as well as *fire*. But, as the celerity it is calculated to produce is unfriendly to the improvements suggested by genius, though useful in conducting every merely mechanical operation, possibly to it alone must be attributed the continued adherence of the workmen to old and faulty practices.

(660.) *Baking biscuit ware*.—This *first* baking is not with grammatic accuracy termed *biscuit*; (*bis coctus*;) but the application is regarded as having originated in the ware presenting to the view, and also to the touch, the dry and rather rough surface observed on sea bread.

The common oven remains as it has been used ever since the *salt glaze* ceased among the manufacturers. The *improved* oven is of recent adoption. Their characteristic difference is in the construction of the *hearth*, or what some might be disposed to call the *plinth*, which part of the fabric we shall fully describe.

In the common, and also in the improved ovens, the hearth *M* (pl. xlix. fig. 1, and 2.) is of very substantial brickwork, and, according to the size, from twelve to eighteen feet diameter, rising about three feet above the ground. In the upper portion of this brickwork, from a centre *b*, radiate horizontal flues *c*, opening into another *d* around them, also into the *bags* or vertical flues *e*, and the *mouths* or fire-places *f*. The direction of the radiating flues is exhibited, except at *g*, with the manner of their being partially covered, that through the apertures the heat may readily circulate. The mouths *f* of the common oven are on the outside of the plinth, and in number correspond with the vertical flues or bags *e*, with which they communicate. The size is usually three feet in breadth, two feet in width, and thirty inches in height. The opening *f*, for the reception of fuel in the upper part, resembles a horse-shoe, formed with the coping bricks sloping inward, or with a cast iron coping bond. In the front of each mouth, from the ground to half the height, is another opening or draught hole. *R* is the space occupied by the fuel. The avenue from the mouth to the bags and flues in the plinth is covered at the top with a large fire-brick, forming a bridge or arch, and also a small check hole *k*, that can be covered by a common brick during the baking process. This large brick has a peculiar shape, and is twenty-two inches long, eight broad, and six thick at each end, but about eight at each side of the groove, which is five inches wide. The section is at the height *V V*, in the direction *X X*, dividing the area into two equal portions. The part down to the opening is not given.

The improved oven has the mouths of less dimensions, in shape resembling a *D* reverted, , with a less draught hole, *R*, formed in the plinth, beneath an arched recess of the cylinder *A*. Instead of the check-hole *k*, above the mouth *f*, is fixed in the cylinder an iron frame for a register stove door and catch.

The cylinder *A*, which is the proper cavity of the oven, is of brickwork, about sixteen inches thick, eight to ten feet high, and thirty to forty-five feet circumference. It is erected on the plinth or hearth *M*, which in the common oven is of greater diameter. (The oven used for the baking *glaze* is usually less than for biscuit.) The cylinder is surmounted by a dome *B*, three or four feet high, and in the centre is a circular hole, about two feet in diameter, through which escapes the unappropriated heat, and also the smoke at the commencement. On one side of the cylinder is an entrance, (not exhibited in the

Mechanical
Processes.Baking
biscuit
ware.Description
of furnace,
oven, &c.
Pl. xlix.
Fig. 1, 2.

Manufactures.

drawing,) a large opening through which the oven is filled or emptied, there being steps placed in an inclined plane for easy access. The stopping of this opening is technically called *the clammings* by the fireman. Inside the cylinder are erected, opposite the mouths *f*, the vertical flues or bags *e*, in the common oven about six feet high, and aperture eight by twelve inches. These are much larger in the improved oven, and higher. In different parts of the cylinder are holes, and one in the clammings, through which the fireman can inspect the progress of the baking process, and also draw his trials. To each is fitted a stopper by a luting of clay.

The improved oven is larger and higher than the common oven, therefore it bakes more ware at the same time, (not uncommonly will one hold 1000 dozen, of from six to thirty-six pieces per dozen,) and as the upper part of the cylinder thus approaches near to the wall of the surrounding hovel *m, n*; there is only a little intervening space for the escape of air. The quantity flowing into the hovel is more easily and efficiently appropriated, and the draught being proportionately increased, though the process of baking requires the same duration of time, the quantity of fuel and of labour is diminished.

The whole inside of the oven is constructed of fire-bricks, made of the very refractory clay called *clunch* and *tough tom* by some writers. In Staffordshire it is greyish, coarse, sandy, and strong, alternating with the aluminous ferruginous shale, or with the sandstone bed of the coal measures, and obtained from the bassetings or decomposed portions of the indurated masses beneath them. Its components are silica 60 to 64, alumine 24 to 28, magnesia 4 to 8, and iron 4 to 12. These fire-bricks are laid in a lute of fire-brick clay and sharp sand; and the chief care of the oven-builder is to make every joint in the cylinder so close as to preclude the possibility of any air entering through them into the interior of the oven. The bags are open in their joints, only a sufficiency of luting being used to keep the whole firm in its situation. The first baking will render the whole inside of the oven one compact shell of partially vitrified fire clay.

The outside of the oven is constructed of common bricks, also the outside of the mouths. These, and also the bags and flues, are formed with dimensions of aperture adequate to contain fuel to fully appropriate all the air of the current draught, that, in its circulation through the ample intervals left by the curvilinear figure, elliptical and circular, of the piled seggars, as little as possible of it may escape, and carry away through the hole in the dome a portion of that heat which should be fixed by the baking ware. And, as the expansion during the raised temperature might cause some part of the oven to fail, crack, or bilge out, on the outer edge of the entrance is fixed an iron framework, from which are hooked around the cylinder several strong *tirings* of iron, hoop-wise, at two feet asunder, and also one where the dome commences; and short bars hook into the framework to keep it together and in its place after closing the clammings.

Around each oven, to protect it, and also the fireman, from the action of the atmosphere, is erected a hovel with a square or cylindrical base to the height of seven or eight feet, and then of a conical figure for several yards, as the oven may happen to be for baking biscuit or glaze. To promote the draught, as required in the improved ovens, the aperture at the top of the hovel is

continued in a cylinder *E*, of several feet height. In many hovels for the common ovens, considerable space is left for the passage of a barrow in wheeling the fuel to the mouths *f*, and in the wall *D* are fixed props of wood, higher than the usual height of a man, to bear boards on which are placed new seggars. The hovels for the improved oven are of contracted size, for it is now ascertained (and only very recently has this fact been observed) that this wide space increases much the consumption of fuel by the quantity of cold air constantly ascending and diminishing the draught of the oven.

The seggars are coarse strong vessels, most of them in shape much like a lady's band-box; others are cylindrical, varied in depth from fourteen to eight inches, but the usual size is about twenty-two inches by fifteen. They are made sufficiently thick in the sides and bottom to bear the weight of the vessels placed therein, both before and during the baking process. On the inside of the cylindrical seggars for plates, and some of the others for large dishes, are fixed three strips of the same material, perforated (prior to fixing) with triangular holes, in two rows, alternately of an intermediate height to the other, in which can be inserted *stilts* formed of clay with excess of flint present, to keep the pieces of ware asunder while baking. The marl used in forming the seggars is the grey silicious shale and the carbonaceous schist, both rather gritty, but ductile and very tenacious, found between the strata of coals in all coal fields; both being technically named *marl* to distinguish them from *clay*, the material of the body. The disintegration of the marl is promoted by being exposed to the atmospheric action, or well *weathered*, and passed between strong iron cylinders before it is used. Some very opulent manufacturers regard, as more economical, the practice of working the marl by manual labour upon a suitable plot of land, where it is exposed two or three weeks. The seggar-maker is careful to adapt the proportions of his materials to the nature of the flint or porcelain ware made; and never have these been found defective, unless there has been present some extra dose of alkaline materials unknown to him, and to counteract whose fluxing powers he had not introduced an adequate supply of refractory components. The usual proportions of materials, to render the seggars refractory during the most intense heat of the oven during the baking of the ware; and, while protecting the contained ware from any injury by the carbonaceous particles of the smoke, the sulphur of the fuel, and the direct operation of the flame, remain so adhesive as not to sink under the weight of the ware, and so porous that the atoms of oxygen may permeate the whole during their fixation by the radiation and motion of heat; are grey marl 50, black marl 25, and ground seggars 25; the latter being used to increase the firmness and durability, and an additional dose being added to strengthen the bottom. Seggars thus fabricated will sustain, not only twice or thrice using, (as stated in some Works,) but many repetitions, until injured by accident,—inseparable from so fragile a manufacture.

Before any ware is placed in the seggar, the outside of the bottom is washed with a mixture of litharge 85, flint 15, in water; and the inside likewise with one of these mixtures: *viz.* smelted lime 80, salt 13, potass 7; or, slip 13, cream colour glaze 43, lime 44; or, 40 lead, lime 42, slip 8, Cornish stone 10. Otherwise the edges of the ware would suffer injury.

Over the bottom of each seggar for biscuit baking of

Mechanical Processes.

Manufactures.

flint ware is strewed a thin layer of fine grit sand (from the silicious rocks in the vicinity of the pottery towns), to prevent the pieces of ware touching and adhering. But, for the soft porcelain, which would be liable to *wauve* or alter its shape by baking, there is a necessity for each article to be firmly imbedded in a quantity of dry flint, by which the proper shape is preserved. This is one cause of the very high price of fine pieces of this kind; and will show the great advantage of the hard porcelain of the Middletown Hill kaolin and petuntse. This can be fired plain, similarly to flint ware, without injury to either its firmness or shape, and requires little brushing to prepare it for the glaze. And as the pieces are thus free from the defects of the other kind, so often seen after even the most careful and attentive manipulations, which enhance to the purchaser the price of the perfect, to cover the expense of the defective, there is general advantage to both manufacturer and purchaser.

The seggars, in *setting-in* the oven, are first placed in the spaces between the bags opposite the entrance. On the edge of each is placed a strip of coarse marl, or strong clay, called a *wad*, on which the next superimposed seggar rests, and is imbedded; and thereby should completely close the interior of that beneath, against the entrance of sulphur, smoke, or flame, which would injure the ware during the baking. Their like size, and flat bottom, are thus useful, for each is a cover for that beneath, and then they are piled up in *bungs*, each of some height, or several *rings* of seggars, before another is commenced; while pipe seggars are fixed in different parts, for the more ready circulation of the heat; each *bung*, from the bottom to the top, becomes, during the baking, one compact mass, and the ware is protected against the carburetted hydrogen evolved from the coals. Over the uppermost seggar, when not empty, is placed a (*hiller*) cover, or flat piece of seggar. In succession the bungs are piled up till the oven is completely filled, the bung at the entrance is then placed; the entrance (*clammings*) is then closed with bricks; every crevice is filled and plastered over nearly half an inch thick with mud, to prevent loss of heat.

When the oven is almost filled, the mouths are supplied with a small quantity of burning coals, to which fuel is gradually added, that the baking process may commence very slowly. The fire rests on the ground, in the mouth *f*, and often is heaped up several inches higher than the brick-work; the front aperture is closed with pieces of bricks, between which is ample space for the entrance of a current of air, to promote the combustion of the fuel. Air, however, must always acquire the temperature of 1000° Fahrenheit, before it can support combustion, and its great power at this degree is every day exhibited at the smelting furnaces in the iron districts; consequently, the more quickly this can be obtained, the greater would be the advantage to the baking. Its long contact with the oven, before entering the mouths and flues, is proportionately injurious; and the more it can be previously heated the greater will be its utility. The greatest quantity of heat, from the smallest quantity of fuel, can be obtained only by carefully adjusting the arrangement and direction of the flues to the size and shape of the furnace, and the kind of fuel used. The fuel is cast *upon* the top of the mouths, to regularly supply the fixation of the oxygen, by flowing through the front holes *h*, more efficiently and economically than when cast *in* below. The opinion

that the efficiency of air for combustion results from its density, governed by temperature, a greater supply resulting when this is low than when it is high, is opposed by the facts, that oxygen solely is the source of heat, and is only one-fifth of the volume of the air; while the other four-fifths are nitrogen, and do not in any way promote the heat in combination with the fuel; then, as the air, entering, abstracts from surrounding substances sufficient heat to rise to the temperature of the baking bodies with which it comes in contact and unites, forming some compounds of less specific heat than that of their separate components; some of which, as gas, evolve through the flues and dome, the nitrogen should be prevented carrying off in that manner any portion whatever of the heat. Therefore, while a given quantity of fuel employed at one time will merely produce the heat, not augment its temperature, the introduction of air by some means raised from 60° to 600°, or 1000°, in its passage into the mouths, would as well save all the heat requisite to raise it so high, and greatly increase the intense powers of the fuel. The rapid strides of chemistry towards perfecting manufactures must gratify every friend to improvement; and we may look for great advantages to the Art, from the discoveries in reference to combustion of Rutter, Whitty, Cheverton, and others.

The heat passes along the horizontal flues *c*, and ascends through the apparatus *g* in the hearth, also through the pipe seggars, as well as up the vertical flues or bags *e*, and permeates the whole mass contained in the oven. When there is a deficiency in the supply of oxygen for the interior of the oven, not only is there a very imperfect combustion of the smoke, proportionately limiting the heat, that is so very requisite to be increased; but also, there escape from the hovel immense volumes of inflammable matter only partially burned; and the ware frequently is so discoloured as to require washing in a mixture of nitre and water, and a second baking. The current of heat is more violent through the bags *e*, than the flues *c*, during the general period of baking; but as uniformity of heat is of primary importance, the fireman by properly using the perpendicular check flue *k*, by the brick being either on it, or removed off, he can alter the direction, as well as the force, as requisite, at the bottom or the top of the oven; for by opening this small flue, an additional current of air rushes in, and the heat passes more violently through the horizontal flues *c*. The temperature is very slowly raised for about twelve hours, then regularly urged, according to the nature of the vessels in the oven; and the time required for baking biscuit is from 33 to 40 hours, for porcelain, and 40 to 48 for flint ware; for glaze, 18 to 25, porcelain; 15 to 20 flint ware. A judicious fireman, aware of the contents of his oven, and the coals he is using, will judge tolerably well of the state of the baking merely by inspection, attentive practice enabling him to judge of the degrees of temperature; and he will keep up the high heat its requisite time, and produce excellent ware, often saving in fuel more than the amount paid for his labours. But when the baking devolves on a less experienced or negligent fireman, he too frequently conducts the progress irregularly, and loss ensues; also from *short firing* of pieces, placed in situations deficient in heat; for if the heat be not sufficiently high and long continued, the ware will be very fragile; and if it be too great, or be improperly continued after gaining the requisite high temperature, many

Mechanical Processes.

Manufactures.

of the articles will be fused into a shapeless vitrescent mass. Those bodies which do not flame, when made red hot by continued accession of heat, are without hydrogen, or want power to fix oxygen, so as *per se* to continue the heat. The silicious mass becomes red hot, and continues so by constant heat without producing chemical changes; whereas the fuel, or coaly mass, when hot, evolves hydrogen gas, which, combining with oxygen gas, produces compounds, and feeds its own heat, as long as the hydrogen is evolved and the oxygen is fixed; and then the oxygen, no longer in gaseous motion, by its condensation becomes radiating heat; and the process continues as long as any hydrogen is evolved by the heat of the fixed oxygen, and as any oxygen remains to be fixed.

For the proper management of the baking, a very accurate acquaintance with the appearance and precise duration of the successive rises and degrees of temperature of the interior of the oven, viewed through the small holes in the cylinder, is indispensable to the fireman. He will gradually raise the oven and its contents, from the commencement; adding fuel as the rarefied air circulates and evolves through the dome, the draft increasing till all is at a red heat; increased supplies of fuel raise to a white heat, which is kept up a certain number of hours; and then the mouths are stirred, and charged with fuel, for the *firing-up*, or highest rise of the temperature, to complete the baking, which expelling from the components of flint-ware and soft porcelain all moisture, without fusion, which would render the ware fragile and brittle, the biscuit-ware is so agglutinated as to be properly hard, compact (porcelain semi-transparent) porcelain completely vitrified, and the glaze perfectly vitrescent. He then quickly abstracts all fuel, *draws the mouths*, closes all apertures with bricks, and plasters all joints over with mud or coarse clay; to prevent entirely any loss of heat, as well as any ingress of air along the flues and bags. The oven and all within it are left to cool gradually to a certain degree, and then the entrance is opened; that is, the *clammings are pulled down*; and after a few hours' longer cooling, the seggars are taken out and emptied of their contents. The ware would rift and craze much, was it to be taken out before the whole was down to a low temperature; but this particular is not always regarded in flint-ware manufactories.

There certainly is great need, yet there is no practice of baking by a *pyrometer*; and hitherto, not one has been submitted calculated to indicate correctly the commencement, and precise duration, of the several degrees of temperature, from a red heat to a white, and the continuance of this latter during the baking process. This was attempted by Thomas Massey, Wedgwood's chief fireman, on the principle of the *contraction* of a prism of clay, deduced from that of vessels according to their situation in the oven; and experience rendered him so correct, as never to fail in baking biscuit, glaze, or enamel colours; but no inducement, to his latest moments, could cause him to divulge his secret to any person whatever. His brother, Richard Massey, stated that the prisms were 67 queen's ware, clay slip, and 33 china clay slip, dried in a mould, and formed by the squeezing box; then cut to proper size, made red hot, and adjusted to a gauge. Massey's gauge, now kept by his nephew at Burslem, is a flat piece of well-baked mortar-body ware, about 7 inches by 2 in superficies, and five-eighths thick; in which is a groove 6

inches long, $\frac{5}{8}$ wide at one end, and $\frac{1}{8}$ at the other, and graduated into 180°. The theory seemed plausible; but it has sunk before the fact, that prisms from the same mass of clay have contracted in different degrees in the same heat; and others have not differed, in very different heats and places.

(661.) *Pyrometrical beads*, technically called *trials*, used by the potters' fireman, are made in the form of small hoops, of Egyptian black clay, or of small gallipots, of the common red brick clay found in the neighbourhood. These long experience has shown vary in tint or colour as they contract by the varied degrees of temperature during the baking; and which tints are compared with another properly baked standard trial, to indicate the relative heats. They are placed in a seggar opposite the hole in the cylinder, and are drawn out at different times by a long iron rod. This method is so far useful as it supplies a criterion for the state of the baking at its termination; but it is completely defective in reference to the positive heat of the oven, and the duration of each rise in the temperature.

The *seggar* clay bears the most ardent heat of the oven uninjured, or at any rate without fusing; and, being very cheap, failure is not important. Of this, form a tube of half-inch bore, and 16 inches long, place it near the hottest part of the oven, so that in it, on two or three props of the same substance, may rest a platinum bar, with the inner end against the bottom of the tube, and the other placed to act against the long arm of a compound lever index, constructed with an arc scale graduated to 180°, each equal to 150° Fahrenheit. The platinum bar could be inserted at any period of the baking, and would always indicate the true temperature, as soon as it had acquired that of the oven.

But for utility, accuracy, and convenience, the best pyrometer is one proposed and invented by M. Achard, Berlin, and which may be constructed by any porcelain manufacturer. Of felspar infusible porcelain, by the squeezing box draw out a half-inch bore of tube, and afterwards flatten this a little so as to present an oval figure; to one end of this fix a two-inch bulb, and then bake the instrument at the highest possible heat of the oven. Mix purified metals, (as bismuth 50, tin 30, lead 20,) which will be fluid at 212° Fahrenheit. Put a certain quantity in the ball up to a mark, zero 0°; reduce the temperature to 62°, the intermediate space divide into three degrees, which may be subdivided into 5; and then graduate all the stem upwards, by the same scale, each of which will be equivalent to 50° Fahrenheit, and the subdivisions to 5 each. Of similar infusible porcelain form a strip, the bottom like a cork, to rest on the metal; and a flat stem perforated with a hole corresponding to each 2 degrees. Then, assuming that the metals *expand* agreeably to an immutable law, the heat acting on the metallic alloy will indicate, through the holes of the stem as it rises, as well as through the transparent tube, the temperature of the situation of the ball. Thus will the expansions supply a standard for comparing the heats of the ovens, for biscuit or glaze baking, by the men in charge, under any and every circumstance. Agreeably to these, there is every probability that the annexed will be the numbers for the several results; (biscuit and glaze bakings;) the temperature at which mercury boils = 13°; zinc 14, antimony (the red heat, of daylight) 19, burnishing gold 32, silver 36, enamel colours 37, lustre 40, copper 44, gold 50, delft ware 108, and 103, iron welds 130,

The only difficulty (and it is one) is the liability of the above given compound to dissipate by the high heat. Gold would not do so.

Dipping
and baking
glazed
ware.

(662.) *Dipping and baking glazed ware.*—When the biscuit oven is *drawn*, the ware is carefully lifted from the seggars into baskets, and carried into the sorting room or biscuit warehouse, where each article is examined, and tried by its *sound*, whether fit for further processes; and then it is put aside till wanted. Each cracked vessel is consigned to the sherd-heap (*shord-ruck*.) Biscuit porcelain has great resemblance to fine statuary white marble, without lustre on its surface; and the figures and vases formed thereof, at the continental and English factories, have beauty and elegance in accordance with the quality of the components to properly exhibit the elegance of the workmanship, preserving all the edges and lines sharp and clear, like to fine sculpture, not possible to be attained in glazed ware.

The very coarse ware, usually with a *black* or *brown* opaque glaze, is only once baked; the vessels in the clay state being coated with the fluid mixture of lead ore and manganese, in water; or black oxide of manganese and galena are pulverized, and put into a coarse linen bag, which allows the particles to pass through in dust on the surface of the ware. The fluid mixture is poured into the vessels, quickly thrown around by a dexterous movement of the hands, and then poured out. The vessel thus coated is placed to dry, and the whole becomes one compact mass by baking. Small porringers, thus made, must not be used for any kind of *sour* or acidulous liquids, as the lead glaze is thereby destroyed; and the metal, dissolved in the liquid, if taken into the stomach, will be very deleterious.

Salt glaz-
ing.

(663.) *Salt glazing* is practised chiefly at the manufactories at Lambeth, Chesterfield, and Belper. The sides of the seggars have several holes in them; and when the ware is at that degree of heat requisite to dissipate all the water of the alumine, a mixture of 98 common salt, and 2 deutoxide of lead, is cast in small quantities into the oven, through square holes above the bags; and the additional heat thus obtained, and alkali supplied, promotes the fusion of the silica on the surface, and thereby covers the vessels with a vitreous coating, coloured a little by the iron in the earths used. When the practice prevailed in Staffordshire, at the time of casting in the salt, a dense white vapour arose, which enveloped the district so completely, as to equal the most dense fog of November known in London; and many ludicrous occurrences are yet remembered, and commented on by the septuagenarians.

The process of *washing* the vessels (in the clay state, but moderately dry) with a mixture of components vitrifiable by a moderate heat, as the ware was being baked, was the first to supersede the use of salt in glaze. The great inconvenience of this process was not long in suggesting a different and efficient method of applying the glaze. The clay ware will neither bear washing nor dipping, in the fluid mixture of vitrescent components; for the water is so quickly absorbed by the alumine, that

the vessels become soft, and by bilging or sinking, irreparably alter in shape or figure; and even if these defects did not ensue, the clay state is too fragile to sustain the manipulations of the ornamental department, painting, and transferring the impressions taken off engraved copper-plates. The biscuit-baking process is therefore indispensable to adapt the ware to sustain these uninjured.

Even when the ware has been baked biscuit, its dry appearance will suggest, and its bibulous nature, from the presence of alumine, on immersion in water, will demonstrate its porosity, inconvenient, for many purposes of utility, and occasioning rapid decomposition. This inconvenience has been understood by all manufacturers of earthen vessels; and the necessity as well as utility of a preservative covering, led to the employment of a glaze applied to the biscuit ware. It was requisite that its bibulous and permeable nature should imbibe the water of the mixture readily, and leave the surface covered with a thin coating of components, readily drying into a solid shell of uniform thickness over all the parts, sufficiently hard not to be rubbed off, but remain permanent, while the vessels are being placed in seggars, kept asunder by cockspurs, stilts, triangles, &c. while again exposed to the *glaze-baking* process, at a white heat, for many hours continued, of all inside the oven, bags, seggars and their contents, by which the components during fusion incorporate with the surface; and at the completion of the process, that the ware should be covered with perfect glass, promoting the durability, and improving the appearance.

The components of the glaze are mixed, either, as *raw*, when they are not fritted together and pulverized prior to grinding; or as *fritt*, when previously brought by heat into chemical combination. The glaze is ground in a vat into a semi-fluid; and when other components have to be added, as white lead, to mix these is used a small hand-mill, (fig. 6.) formed of a strong hooped vessel A, in which works a vertical shaft B, on which are fitted four strong gate-like frames C; the top has a strong iron bevel wheel D, which works into another on an iron shaft that passes over the top of the tub, and has on one end a fly wheel E, four feet diameter, and on the other a winch F, for the workman to turn. From this mixing tub, the semi-fluid (as thin in consistence as is possible conformably to the contractile nature of the body, and proper combination in baking) is put into a dipping tub; and, to render the water more buoyant when using metallic oxides,—whose superior specific gravity causes them constantly to tend to precipitation and continuance at rest at the bottom of the tub; but which should be suspended in the fluid, that the ware may not be immersed in a semi-fluid, in which scarcely any components of glaze are present,—there is used a *flow*; a dose of either common salt, (chloride of sodium,) disregarding the yellowish tint that results from the reaction of the chlorine and the metal, or of muriatic acid, which is prejudicial, because while being dissipated by the high heat of the glaze-baking, away with it goes whatever it held in combination.

Dipping is the technical name of the process of covering the vessels with the substance which by baking forms the *glaze* of the ware. The articles in the biscuit state are carefully brushed from dust, and porcelain from the flint; then the *dipper* receives each large vessel, which he immerses in the glaze tub, lifts it out, and by an adroitness not describable, and incon-

Mechanical
Processes.

Manufac-
tures.

ceivable by persons who have not witnessed the manipulation, he rapidly gives to the article different positions, in order that the covering may be uniform, and the glaze, when baked, may not be thicker in one part than in another; and during the change of position, the water in the mixture is absorbed by the vessel, which is then placed upon a hair sieve, or a board in which are rows of nails with the points upwards, for the superfluous portion of the fluid to drain off. When sufficiently dry to bear moving, the several articles are again placed in seggars to sustain the gloss or glaze-baking.

There is scarcely need for the remark, that the fusion of the components of the glaze by cooling would cause the vessels to adhere, if they had been placed together. To prevent this, by keeping them asunder, and also to present opportunity for the oxygen fixed by the supply of fuel properly to affect the surface of all the ware, between the pieces are placed small separators, named *stilts, triangles, cockspurs, rings, and pegs*. These are formed of clay which contains an excess of flint; and very often the fine points of these are so imbedded in the glaze, that they are fixed therein when cold; and to separate them, they must be broken, rendering the instrument itself useless in future processes, and leaving a mark on the ware, which is disagreeable to the eye, and causes the trouble of dressing which endangers the article itself. Efficiently to remedy this great disadvantage, the following hint is given. Let some fine platinum wire be cut into lengths of one quarter of an inch; and in each point of the cockspur, or triangle, let one of them be fixed while in the clay state, and baking will render it immovable; its fineness will preclude more than a mere speck from being visible; and the cockspur, &c. may be repeatedly used without sustaining any injury.

The frequent expansion and contraction of the brick-work of the oven, and especially the sudden cooling, expediting its destruction, the manufacturer finds it his interest, not only to allow the cooling to take place very gradually, but also to keep up such a stock of ware from his workmen as will allow the seggars to be again filled therein as soon as the oven is sufficiently cool.

Ornamental Manipulations, Components, Proportions, and Processes of Colours, for Blue Painting, Blue and Black Printing, Enamelling, and Lustres.

Ornament-
al manipu-
lations.

(664.) The modern improvements in the embellishing of porcelain and pottery, did not originate with our native potters; for specimens yet remain to prove, that the ware called *faïence*, covered with the glaze of Palissy, agreeably to the processes of Petitot, had been occasionally honoured with the efforts of some of the greatest masters of the art of design. Works on porcelain are extant said to be from the hand of Raffaele and of other eminent painters, and the cabinets of the curious present specimens of British porcelain, with designs executed by our very deservedly celebrated Countryman, Sir John Thornhill.

Solution of gold.—1. In 33 parts of nitric acid, with specific gravity 1.350, and 77 of muriatic acid, of the specific gravity 1.144, at 80° Fahrenheit, dissolve small doses of grain gold till the liquid is saturated.—*Another method*, less efficient, is,

2. In 50 parts of pure water, 33 nitric acid 1.350, and 17 muriatic acid 1.144, at 100° Fahrenheit, dissolve doses of grain gold to saturation; then add 6 parts of nitric solution of silver.

Were these concentrated solutions to be mixed, the result would be a very acidulous precipitate of metallic gold.

Solution of tin.—1. In 77 parts of muriatic acid, of the specific gravity 1.144, at 112° Fahrenheit, dissolve 33 parts of grain tin in doses of 4 or 5 parts at each immersion; and always in day-light, to preclude danger from the evolved hydrogen exploding by a lighted candle coming in contact. The solution thus formed will be clear, and incapable of being rendered curdle or coagulate.—*Another method* is,

2. In 76 parts of nitric acid, and 34 of muriatic acid, (or in nitric acid saturated with common salt, or with muriate of ammonia,) at 112° Fahrenheit, dissolve small doses of grain tin till saturated.

The solution of tin (1.) has the metal in the state of proto-muriate, or *that only* which is proper to be a component of the *purple* for potters' use. Other preparations of gold will form a fine purple, without the presence of tin; and therefore the tin is not indispensable, as it has very slight colouring power; but it is used because of its peculiar property of rendering the purple, of which it is one component, more capable of sustaining the continued high heat of the oven requisite for it to become properly amalgamated with the softened glaze; and it also renders the gold refractory in very high heats, and the proper state of oxidation is preserved by the flux. The solution of tin (2.) has the metal in the state of a hydrated per-muriate, and, from using it in the precipitation of the purple, not only have there been unnumbered disastrous and vexatious results in the processes, but most expensive failures when the work was baked.

The purple colour for potters' use.—To 80 parts of gold solution, (1.) 20 parts of tin solution, (1.) and 1 part of nitric solution of silver, add respectively of pure water at 200° Fahrenheit, 800, 200, and 10 parts. First, mix well the solutions of gold and silver; then stir very carefully with the feather of a strong quill while gradually pouring in the solution of tin; and as the precipitate forms, constantly stir in more boiling water until no more appears, then leave the whole to rest 24 hours or more. Adding carbonate of potass will recover the acids as nitre.

The assertion has been made (but it is not clear how the fact is possible) that, in combining these very dilute solutions, every 1 of gold will produce 5½ of purple. Does the remark regard the combination with a flux? If so, the colouring power of the above purple being to flint glass as 1000 to 1, the results will be much greater; the proportions may be, for mixing, purple 4, or 3, with 96 or 97 of flux, (red lead 76 and ground glass 24, or white lead 58, calcined borax 30, and flint glass 12,) or, purple 15, red lead flux just mentioned 75, white oxide of antimony 10.

Another method, very tedious, is: immerse a plate of grain tin 2 hours in the gold solution; then with a feather clean off the purple; repeat the immersion till no more purple be formed; again saturate the solvent with gold for another course; and when all is abstracted carefully, dry the purple powder.

Some persons use in solution, gold 47, tin 47, silver 6, and the precipitate they flux with borax 53, red lead 37, and ground flint 10.

A purple without gold is formed of manganese 45 parts, red lead 50, cobalt calc 5.

Mechanical
Processes.

Manufactures.

Purple.—Gold 1, flux 3.—Flux red lead 8, glass 7; or, borax 5, flint-glass 16, red lead 5.

Purple lilac.—Pulverize together, and then fuse, manganese 34, best smalts 76.

Purple, (under glaze.)—Fuse together 2 hours, manganese 46, red lead 46, cobalt calc 8.

Purple distance, (enamel.) Mix together enamel purple 12, manganese, oxide of, 18, flux 70, (red lead 25, ground glass 75,) or, gold purple 46, manganese 6, and flux 48, (glass 77, red lead 23.)

Rose colour.—In pure water 95, heated to 190°, mix gold solution 5, add sal ammoniac till no more precipitate appears, then let the liquid remain at rest, at the shortest, 24 hours. By siphon draw off the liquid; and, unless wanted immediately, very carefully wash in great excess of boiling water; and as the precipitate is dangerously fulminative, because the acid is peculiarly affected by the volatile alkali, a plaster slab is best, for many reasons, to receive it to dry, and from which it is brushed with a feather.

For many uses, the precipitate is formed by adding carbonate of potass; and the acid being neutralized by the vegetable alkali in chemical combination, the precipitate is not fulminative, though equal to the preceding.

Keep very cool, and, with a feather, mix, of the precipitate, 3 parts, chloride of silver, 1 part, and 96 of flux, (17 red lead, 50 ground flint, 30 borax.) Or, purple precipitate 3, silver 1, flux 96.

The oxides of iron supply the palette with several different shades of enamel colours, *rose, red, and brown*, changeless, when properly prepared, on either kind of porcelain; and varied in tint by the degree of heat to which the oxide is first exposed. Certainly they are less brilliant than those which have gold for their base; but they are very beautiful, and, on a glaze of Middletown Hill petuntse, peculiarly fine and rich; even on one of artificial felspar they are preferred, because more certain in their application, and improving in brilliance, by baking, when combined with a proper flux. When excess of lead is present in the glaze, the colour suffers in tint to a dull disagreeable hue. The *red* is regarded as resulting from imperfect vitrification, which keeps the particles of the peroxides suspended in the mass; and by mixing varied proportions of the red and the black oxides, are formed the different shades of red, brown, chestnut, chocolate, &c.

The *red* is usually a nitrate of iron, afterwards carefully calcined; and, by raising the heat, brought to *dark red* and brown. In nitric acid dissolve iron filings; with pure rain water dilute; to precipitate the oxide, add bicarbonate of potass, or tartar, whose carbon will aid to dissipate the hydrogen, and alkali will promote the calcination of the precipitate, placed on a sheet of iron, exposed to a clear fire till the powder is a fine red. Grind for use colour 25, flux 75, (of borax 23, red lead 41, ground glass 36; first fritted.) Or,

Calcine some pure table salt; then take of this calc 66, and 34 of the preceding colour; mix well together, carefully calcine, not fuse; pulverize the calc; with boiling water abstract all the colouring particles, which must be left to completely subside; then by a siphon draw off all the clean water; wash the sediment frequently with pure water; and for *rose*, colour 25, flux (above) 75. Or,

Calcine good copperas in an open fire, that only may

remain the powdered peroxide of iron; (which should be bright red, or fine orange, not brown, or cream white, easily formed by excess of heat;) with boiling water, five or six times wash out the sulphuric acid, and dry the powder.

Enamel red.—Calc 25, flux 75, (above,) or, 30 and 70.

Light red.—Calc 30, flux 30, ceruse 40.

Dark red.—Colcothar 20, flux 80, or, 25 and 75.

Pink, (for printing.)—Concentrated muriatic (1.144) acid, saturate with oxide of chrome; and in other muriatic acid dissolve pure tin; to each solution 10, add pure water 90, at 212°; filter; mix well the solutions, and add boiling water till all precipitate is down. Dry colour 25, flux 75. Or, fuse together oxide of chrome 30, oxide of tin 70; or 40 and 60.

Flesh red.—Muriatic acid concentrated, saturate with best black oxide of manganese, then to solution add nine times the quantity of boiling pure water, immediately filter, and evaporate; then in a cool place crystallize. The crystals grind, 50 parts to 50 flux, petuntse 75, potass 25.

Or, (for *filled-up* patterns,) in two quarts of pure rain water, for three hours, simmer or slowly boil, 28 ounces of clean sulphate of iron, and 8 ounces of gum Arabic; reduce to 1 pint, cool, and bottle for use.

The *brown red* colours, from mixing varied proportions of the black oxide of manganese and the brown oxides of copper and of iron, (when fritted with the flux previous to grinding in the mill,) remain unchanged by the baking heat; because the oxide of manganese prevents the lead of the glaze affecting the oxide of iron. The *brown red* ground (French *fonds caille*) is colour 25, best petuntse 75. The russet and tortoiseshell grounds are colour 34, flux (see flesh red) 66; colour 25, umber 25, flux 50.

Purple brown.—Peroxide of iron (red nitrate) 15, flux 85, (petuntse 75, alkali 25.) Or, colour 20, flux 80.

Red brown.—Fritt manganese 64, (or 62,) white lead 12, flint glass 6, (or 7,) flint 12, and borax 6 (or 7.) Fawn red (above) 50, terra sienna 50; grind for use.

Red brown (light.)—Contents of retort, after abstracting oxygen from manganese, 50, and petuntse flux (above) 50. Grind for use. Or, peroxide of manganese 66, oxalate of potass 34, mix well in hot water; filter, add ammonia, the precipitate dry, and grind colour 50, petuntse flux 50.

Mulberry (under glaze.)—Pulverize and mix manganese 54, blue calc 20, borax 12, place on a biscuit dish, and cover with 14 of pulverized nitre; carefully calcine and grind, colour 50, flux 50, (flint 40, ground glass 40, red lead 20.)

Brown (for enamel.) Dark.—Brown oxide of iron 34, flux 66, petuntse 80, potass 20.

Light.—Red oxide of iron 12, yellow (under glaze) 9, calcined umber 9, and flux (above) 70.

Brown (for under glaze.)—Glass of antimony 40, litharge 40, manganese 16, blue calc 4. Or, crude antimony 26, litharge 66, manganese 15, blue calc 3. Or, litharge 48, 28, crude antimony 18, 14, glass of antimony 18, 0, oxide of manganese 13, 14, zaffre 3, 43, blue calc 0, 1. Or, (for *lines*.) 21, 0 49, 16, 0, 7, and nitre 7. Or, 50, 16, 14, 14, 0, 4, colour 50, flux 50.

Brown (for printing.)—Litharge 33, 37, antimony 27, 37, manganese 27, 18, blue calc 13, 8.

Mechanical Processes.

Manufac-
tures.

For *topping*.—Brown (above) 50, 40, orange 16, 8, white lead 8, 20, glass 28, 32. Fritt together.

French brown.—Orange 50, umber 25, flux 25, (red lead 28, glass 65, borax 71.)

Chestnut brown.—Red (above) 25, French brown 75. Grind for use.

The *blue colours* are supplied by the oxide of cobalt, whose tendency to alumine renders them the most rich, fine, solid, and fixed whatever heat may be applied, of all colours on porcelain or flint ware. The pure oxide is used for the very rich and beautiful tints; and for the others, various combinations of the oxides of cobalt, tin, and zinc. But much of the brilliance is dependent on the components of the body, or the glaze, as well as the variety of shades. The alkalis give a deep blue precipitate; fusion with antimony and litharge forms a green; and fusion with manganese and iron a black. The alkaline earths, barytes, lime, and magnesia, affect the cobalt, when sulphuric acid is present, and injure or destroy the printed patterns.

The oxide of cobalt should be completely free from arsenic, to prevent the radiation of the metal by its combination with the alumine of the body resembling smeared writing, and injuring the lines, which should be clear and distinct; or giving a bluish tint to white glazed ware baked at the same time in the same seggar with blue painted or printed. Brongniart first announced this remarkable effect. And also, but without giving the process, that from pure chromate of lead he had obtained a deep fixed blue for porcelain. Yet he has blamed his predecessors for the very same conduct!

Blue.—Pulverize cobalt ore, and well mix. Ore 40, carbonate of potass 40, Lynn sand 14, charcoal 6. Or, cobalt ore 25, zaffre 25, potass 35, sand 10, charcoal 5. In crucibles that contain about 3 pints, put $1\frac{1}{2}$ pound of mixed materials; place these in a muffle connected with a reverberatory furnace; gradually raise the heat for seven hours, then regularly diminish for nine hours longer. When cool, the upper substance will be cobalt and a silicate of potass; and below will be nickel and bismuth. Then pulverize the silicate, and the powder put

In small pint flanced biscuit jars, calc 90, potass 10, about 1 pound in each crucible; raise the heat six hours, and diminish 7; repeat this till the silicate be very pale in colour. Pulverize this calc also. Next,

On biscuit dishes strew ground flint one quarter of an inch thick; on which spread the last calc, and carefully calcine well six hours, to dissipate the arsenic, (which will remain if the calc be *fused*), and separate the nickel. Pulverize the blue calc; and

Mix well, calc 90, best flint 6, borax 4; or 85, 9, and 6 potass.

In a similar way mix like quantities of zaffre and the alkalis, to form a coarser blue.

In earthen cups, half an inch thick, 3 inches diameter, and $1\frac{1}{2}$ high, put of the powder, and place in the muffle; raise the heat 6 hours, and diminish 7; the top will be blue calc, the bottom nickel, and other metallic scoria.

When a quantity of nickel is accumulated, pulverize and mix, metal 80, plaster 12, borax 8, put in cups and fuse 16 hours. The blue thus obtained is usually mixed with the zaffre blue.

Strong (for printing).—Blue calc 40, flux 60. (Petuntse 80, potass 20; or, red lead 18, flint 36, glass 28,

nitre 9, borax 9.) Or, calc 35, 30, and flux 65, 70; or, calc 20, flux 40, and 40 white lead. Or, calc 25, and 35 flint, or barytes.

Weak, (*Broseley*).—Blue calc 20, flux 80. (Flint 70, nitre 9, borax 21;) or, calc 15, petuntse 85.

Blue (for painting or enamel).—Blue calc 25, flux 75, (flint 14, glass 28, white lead 35, nitre 23;) or, 30, 70. (For grounds,) blue calc 45, petuntse flux 55; or, 35, and 65 for Wellington blue. Or, fuse smalts, azure blue, grind, and mix calc 25, flux 75.

For smalts, (for printing glaze,) fuse together cobalt calc 10, borax 30, glass 60; or, zaffre 20, potass 20, flint 60.

Sky blue.—Fuse together two hours, copper filings 10, soda 40, flint 50.

One of these fritts is occasionally added. Zaffre 20, black flux 80, smalts 12, soda 88, oxide of cobalt 26, glass 54, coal 20.

Cobalt ores are found in several places in England; yet, although there is so great a demand for the calc weekly, they are not collected. A few years ago, a Company for this purpose was formed, and their produce sold at the average price of 47s. 6d. per pound; but the prejudices of the potters, and the want of chemical knowledge, neglect, or how to produce *matt blue* (pure calc) from the refuse scoria, rendered the concern unprofitable; and zaffres continue in demand for the preparation of the colour.

The *yellow colours*.—Before modern chemical research for cheap and facile processes supplied means for readily and cheaply obtaining chromic acid, the enamel yellows were formed of varied proportions of oxides of lead, silver, and antimony; and required very careful management of the processes, to prevent the lead losing its oxygen, and causing black specks.

Upon glazed flat dishes spread iron filings; sprinkle with water to oxidize them; wash off the oxide, and again sprinkle; when the oxide has settled, by siphon draw off the water; dry the oxide, and in a covered crucible calcine at a moderate heat, from 4 to 8 hours, according as the tint is required to be brighter or darker. Colour 40, flux 60.

Yellow calc.—Litharge 17, 48, antimony 17, 36, lead ashes 33, 0, oxide of tin 33, 16.

Base yellow.—Pulverize, mix, and fritt white lead 40, tin ash 40, litharge 10, antimony 10.

Yellow.—Fritt red lead 80, antimony 10, oxide of tin 10, colour 40, flux 60.

Orange (enamel).—Fritt red lead 60, antimony 20, flint 15, red oxide of iron 5; for use grind together, colour 28, flux 72. Or, Naples yellow 35, flux 65.

Orange (under glaze).—Mix and fritt, litharge 46, 55, antimony 30, 32, oxide of tin 8, 0, brown oxide of iron 16, 13. Grind for use.

Naples yellow (fine gold).—Mix well together, and carefully stir while calcining for not less than three hours, white lead 75, 70, 76. Antimony 11, 20, 16, alum 4, 5, 4, and sal ammoniac 7, 5, 4. Colour, Naples yellow 30, flux 70.

Chrome yellow, the most brilliant colour; an insoluble compound of a metallic acid and a metallic oxide, more beautiful and durable than any of the ancient yellows, and much superior to compounds of oxides only; as, when red oxide of iron is employed to heighten the tint, its colouring power suffers under fusion with lead.

Mechanical
Processes.

Manufac-
tures.

Nitric acid saturate with lead, to solution 10, add pure water 90; then add solution of chromate of potass till all the metal is precipitated; let the liquid stand 24 hours; draw off the water, dry the precipitate, and mix for use. Colour 50, flux 50. Or,

One pint of pure water saturate with acetate of lead, add 16 ounces of ground carbon of barytes; boil, and add half an ounce of chromate of potass. Settle 24 hours; draw off the water, and dry, for use.

Nasturtium.—Chrome yellow 24, flux 76.—(Fritt, separately, glass 10, 3, lead 3, 2.)

Straw colour.—Oxides of lead and uranium 50, and 50, grind together. That of titanium supplies a pale dull yellow ground.

The *green colours*, from oxide of copper, or yellow and blue mixed, to prevent them assuming a black tint are fritted with their flux prior to grinding; and, thus prepared, they remain uninjured by very high heats.

To a saturated solution of acetate of copper, add carbonate of potass, and keep the quick precipitate separate from the sluggish; the former supplies a brilliant fine green; the latter one olive, dull, and earthy. Other shades are obtained by similarly treating saturated solutions of muriate and arsenite of copper.

Olive green (for grounds).—Fritt flux 50, blue calc 20, oxide of nickel 30; or, chrome yellow 30, carbon of barytes 8, damp blue 60.

Blue green (enamel).—Very carefully fritt. Red lead 40, 50, glass 12, 0, flint 14, 18, borax 9, 16, copper calc 7, 8, yellow calc 5, 8, white enamel, 10, 8. Or, for

Yellow green—40, 12, 14, 4, 9, 10, 11. Or, blue green fritt 88, enamel yellow 12. Or, white lead 42, flint 12, borax 22, glass 9, base yellow 12, copper 3.

Grass green.—Blue green fritt 77, enamel yellow 23.

Fritt oxide of nickel 80, nitre 20, supplies the brilliant emerald green of the Sevres porcelain, and will bear uninjured any degree of heat.

Green (under glaze).—Biscuit yellow 87, blue calc 13. Or, yellow calc 60, blue calc 8, white enamel 20, flux 12.

For edging, (under glaze,) enamel blue 10, oxide of tin 15, flint 20, glass 30, copper calc 25, colour 50, glaze 50.

Celeste blue green.—Chrome yellow 20, 25, 30, Prussian blue 80, 75, 70. This is best on a petuntse glaze; on others there is deficiency of brilliance.

Oxide of chrome, which sustains any heat without injury, is now very generally used in the manufacture for a *green*.

In concentrated muriatic acid dissolve, till saturated, oxide of chrome; to solution 10, add 90 pure water at 212°; filter, evaporate, crystallize, and calcine the crystals. Colour 50, flux 50.

Or, chrome yellow 80, arsenic 10, potass 10. Arsenic is not desirable.

The *black colours*, alike beautiful and excellent, are formed with difficulty, because no metallic oxide, *per se*, is really black; platinum gives the best, manganese the next, and that from iron is opaque, dull, blistering, and easily becomes reddish. The general practice regards the compounding chemically the oxides of manganese, cobalt, and brown of copper; and when used with a petuntse flux, or on a petuntse glaze, the colour

is brilliant; but on other glazes, much attention is requisite to prevent the colour scaling off and becoming dull.

Black (for enamel).—Fritt, borax 32, calcined umber, best, 16, red lead 20, enamel blue 16, flint 8, blue calc 8, colour 25, flux 75; or, oxide of manganese 8, iron 8, copper 8, cobalt calc 8, glass 52, nitre 16; or cobalt calc 30, umber 36, oxide of copper 34. Or,

Muriate platinum dilute with pure water, add dilute solution of nitrate of mercury; by a clear fire volatilize the mercury from the precipitate, and use colour 25, flux 75, glass 90, nitre 10.

(For *black printing*.)—Of the first above 80, enamel blue 10, enamel purple 10; grind for use. Truly excellent and brilliant for landscapes and flowers on a petuntse glaze. Or, calcined borax 46, calcined umber 36, blue calc 18. Or, 15, 57, 12, and 16 red lead. Or, oxides of cobalt 66, nickel 34.

(For *printing*.)—Fritt. Red lead 60, antimony 25, manganese 15; then add blue calc 40, oxide of tin 5, and grind for use. The cobalt has the same tendency to strike manganese *black* as alumine *blue*.

(For *lines*.)—Copper calc 25, flux 75. Or, 30 and 70. Or, 40 and 60.

The beautiful *black* on the Sevres porcelain, which, because of its petuntse flux and on a petuntse glaze, will sustain the highest heat, is cobalt calc 26, black oxides of iron 36, and of manganese 38.

The *pure white colour* is obtained by rather an operose process. In distilled water dissolve 1 pound (or more *ad libitum*) of good table salt; filter, evaporate, and decrepitate; or filter, partially evaporate, crystallize, and use the cubical crystals. In a fire place a covered crucible, and when red put in a certain weight of block tin, with which, when red-hot, mix well twice the weight of the preceding salt; cover very closely, often stir with a clean red hot spatula; and when its end becomes white, from 60 to 80 minutes, the calc is ready for the next process. Pulverize and pick very clean the calc; again put it in a covered crucible, and raise the heat three hours; when cool wash away all the salt left; boil the residue violently two hours; decant, let the solution rest twenty-four hours, and draw off the water. Colour grind for use.

Chloride of silver.—In concentrated muriatic acid 25, diluted with pure water 75, at 212°, dissolve silver till saturated; then add for 10 solution 90 water at 212°. With common salt, well stirred in, precipitate the metal as chloride of silver; let the whole rest two hours, draw off the liquor, and wash the precipitate until quite insipid. This is a component of the best yellow colours of the early hard porcelain, and of the yellow stain for glass.

Silver (for *burnishing*, or *black Egyptian*).—In concentrated nitric acid in a sand bath dissolve 32 grains of silver, then add to solution 8, water 92 at 190°; insert a plate of polished copper twelve hours, decant the water or filter, wash well the precipitate, and dry for use. By iron filings precipitate the copper as a rich and fine *bronze*. Grind for use ceruse 20, silver 80.

Gold (for *burnishing*.)—To solution of gold 75, and muriate of silver 25, water at 212°, 900; add a saturated solution of proto-sulphate of iron; as long as there is any precipitate stir well together, and let the whole

Mechanical
Processes.

Manufac-
tures.

rest twenty-four hours; decant the liquid, wash the precipitate well, dry, and use with nitre or borax as flux. Or, to solution of gold 77, ditto silicate of potass 33, add muriatic acid till precipitation ceases; wash and dry for use; metal 6, flux 94. Or, gold 80, silver 13, oxide of bismuth 7; grind, metal 26, flux 74. Or, gold 66, mercury 34; then metal 20, black flux 80, of 33 nitre, and 67 bitartrate of potass. Or,

The solution of gold, evaporate dry; well wash in great excess of pure water, gently heat to 130° , gradually add a solution of caustic potass till all the gold precipitates of an orange tint; let it settle twenty-four hours; by siphon draw off the water, and then evaporate the precipitate. The gold must not be dropped into the potass, else it will become blackish-brown, because of the alkaline nature of the menstruum, and the acidulous property of the gold. The gold is used for some purposes, with a certain proportion of flux, to fuse with the glaze of the ware. The proper management of the gold in these processes, to secure that state of peculiar comminution in which it can be used to the best effect with economy, requires great attention, and must provide antidotes for injury from excess of heat, hydrogen, or carbonaceous vapours. The weekly consumption of gold in Stoke-upon-Trent Borough is about £650 sterling, or £35,000 per annum.

The colour-mill is a strong box, in which is fixed a block of chert or quartz, hollowed like a shallow bowl; in this fits a smaller block, with the under surface to fit to the bowl, and the upper perforated for the square end of an upright shaft to rest in and move this block. The calc and flux are thus ground together in water for about six hours.

After the colour has been ground at the mill it is usually dried well, and is next put on a very smooth and hard stone, and with a muller ground in water or oil as proper, until it is free from the least perceptible roughness, either under the muller or between the fingers.

Blue Painting.

Blue
painting.

(665.) The earliest method of ornamenting flint ware, table plates, &c. was by colouring the grass-work on the edge of the flanch green by oxide of copper, or blue by that of cobalt. Neither this nor the painted border required or exhibited much taste in the pattern or ability in the execution. Subsequently, these were superseded by lines of blue or brown, formed as the plate was in motion on a whirler, (described in the Enamelling Manipulations,) and ware thus traced is called brown line ware.

This method of ornamenting common flint ware is adopted for patterns most in demand by the labouring classes. At first these patterns were very rude imitations of the uncouth and unmeaning designs and figures seen on old blue porcelain; and in both originals and copies truth was outraged and taste disregarded. A better style was adopted by Wedgwood, who excited attention to finer compositions, and to correct taste, by rejecting those patterns and substituting copies of drawings of British plants and flowers on his tea services. Young women trace them with camel hair pencils on the surface, and have to exercise considerable care, because every stroke of the pencil remains permanent on the ware, and cannot be erased as in enamelling.

The colours are ground in water, and worked with a little gum or sugar rubbed on the palette. Mechanical Processes.

Flint-ware in the biscuit is now ornamented by either the pencil or by a great variety of elegant patterns neatly engraved on copper plates, from which impressions taken on paper are transferred to the surface of the vessels, and blue being the colour first used, these manipulations are named blue painting and blue printing. For several years only two patterns were used in printing; the willow for table ware, and the Broseley for teas. But latterly numerous others have been introduced.

Blue Printing.

(666.) The printing press used for this purpose consists of two iron cheeks, five feet high, one foot broad, one inch thick, strengthened in the parts where strength is required. These stand vertically on the plinth or foot, fixed by screws about two feet distant, kept asunder and firm by a bar below and the head-piece above. Each cheek has two apertures for brass steps for the axles of the two iron rollers, preserved at a proper distance and secured by stout screws. The iron rollers are about 22 inches long, 1 thick, and 30 in circumference, with three folds of blanket almost round the upper fastened by cords. The axle of the upper has one end passing to the outside of the cheek with a square end for fixing a lever to turn the roller, rather more than the plate is in size, and, by the motion, turns the lower roller, so as to draw in or expel the plank or iron plate about 1 inch thick, and 28 by 22 inches surface.

The press is placed for convenience very near a stove of thick iron plate. On this stove the printer places his copper-plate, while he rubs the colour into its lines by a leathern rubber rolled and firmly tied together. The metallic calc which forms the colour in the requisite proportion is well ground with an oil on a very hot plate. The oil is often prepared according to the humour and whim of some self-consequential workman; but we have never heard of the following being inefficient. In a covered jug over a slow fire for two hours boil 1 quart of pure linseed oil, and when the oil is not pure but throws up a scum, carefully take it off; (some printers at this stage put in gradually 2 ounces of red lead, and burn off the greasy particles;) add 1 pint of best rape oil and 2 ounces of copaiba balsam, boil slowly two hours longer, cool to 160° , and add half an ounce each of amber oil, white lead, and clean pitch; again raise the heat to 212° , and continue it 45 to 75 minutes for weak to strong tints: or, linseed oil 1 quart, rape one quarter of a pint, copaiba balsam 1 ounce, tar one quarter of a pint, and balsam of sulphur carefully introduced to prevent the whole coagulating; or, 1 quart linseed oil, 4 ounces of the flowers of sulphur, 2 ounces of rosin, 4 ounces of balsam of sulphur; or, linseed oil 1 quart, red lead 2 ounces, Barbadoes tar 4 ounces, balsam of sulphur 4 ounces, and half an ounce each of rosin, acetate of lead, oil of amber, and copaiba balsam.

While the printer rubs in the oil (or colour) the plate becomes so hot as to render the use of thick pieces of leather indispensable on the thumb and fore finger of the left hand. The oil is scalding hot, and the plate is cleaned first with a palette knife, very broad and thin, then with a well-stuffed leathern boss; the plate is then placed on the plank, a piece of moistened tissue paper is brushed over with a very strong soap lie, then laid on the hot plate; both are run through the press: on the

Manufactures.

return the paper is rendered dry by the heat, and so imbibes the oil of the colour, yet leaves the colour distinctly adhering agreeably to the pattern. Very recently Messrs. Machin and Potts, of Burslem, have obtained a patent for printing the impressions for this purpose, by a machine and cylinders, something similar to cotton calicoes. The secrecy observed prevents a description being given here, but the results are entirely satisfactory to the patentees. The impression is received by a little girl, the *cutter*, who immediately cuts away all the white paper, separates the several parts, and places them so that they can be readily taken up by the *transferrer*, who performs the manipulation of fixing the pattern on the vessel. This requires much tact and judgment, equally to avoid breaking the vessels, as to ornament them with the design engraved. A roll of flannel, in length from 6 to 16 inches, is firmly tied together into a rubber; the ends are left soft, one to rest against the hollow of the right arm-pit, and the other to act upon the paper of the impression. The transferrer takes a biscuit vessel, places the several portions of the impression in their situations, at first gently, and afterwards most forcibly, rubs the whole upon the surface, until the paper is almost rubbed into the substance of the ware, whose absorbent property receives the oil, while the cobalt and alumine combine by their peculiar chemical tendency for each other. The vessel is afterwards placed on a board, and when a certain number is finished each is immersed in a tub of water, and a brush and a little soft soap are used to wash off the paper, and leave little beside the mineral colour.

When the ware has been treated in this manner, it is placed in a highly heated room, where it is made very hot, to evaporate the water imbibed by the biscuit ware, then for hardening on it is made red to volatilize the oily and destroy the carbonaceous particles. Both these processes are indispensable, as the omission of either would leave existing an obstacle to the proper adhesion of the watery medium of the *glaze*, when the ware is immersed to receive that necessary coating.

The workmen in France substitute for tissue paper a thin layer of glue, as will be now described under what English workmen denominate

Black Printing.

Black printing.

(667.) This manipulation is adopted to transfer to the glazed surface patterns from copper-plates, different in design and execution from those adopted in *blue* printing. The workman boils a certain weight of glue in a given quantity of water from four to six hours, so that when it is poured out on large and well-glazed flat dishes, in sheets of about a quarter of an inch thick, pieces of it will be completely flexible, yet have the consistence of dressed leather. When the glue is cold, the workman cuts the sheets into pieces of the size of each plate, the technical appellation *papers* being applied by some, and *bats* by others. The metallic calc used for the colour is rubbed in a saucer till completely dry and in the state of an impalpable powder, and a lock of dry carded cotton is used to apply it. Each plate is secured with rosin to a small prism of wood, for the convenience of holding in one hand, while with the other the oil is rubbed into the engraving, and the outer edge neatly cleaned. (For *Oil* see the recipe already given.) A glue paper is placed on a flannel fastened over a semicircular block of wood; on this the plate is pressed with a force sufficient to ab-

stract out of the lines of the plate the oil rubbed therein. The plate is laid aside, and the paper is applied by a gentle pressure to the surface of a vessel, then carefully taken off and applied to a second vessel, (where the work is of the usual kind;) the paper is then cleaned with a damp sponge and left to dry. The vessel is taken up, and, with the cotton, the colour is applied to the moistened surface; other vessels are similarly submitted to the papers until these require longer time to resume their adhesive power. The printer then cleans off all the superfluous colour with old silk rags, and with others wipes all the surface to which any particle of colour might possibly adhere.

Much tea ware, after being printed by either method, undergoes a further process, the upper edges being *topped*, and certain parts *lined* with gold or other colour. Any other ornaments deemed proper are added by the artists, and when dry, the articles are placed in those parts of the muffle where proper heat will be applied in the final process of baking the enamel.

Enamelling.

(668.) Whatever colours may be required by the design, Enamel landscapes, flowers, or figures, with which the porcelain is to be ornamented, the artist mixes a small quantity of each, according to its nature, on his well-glazed earthenware tile, with the smallest portion of oils of tar and turpentine, proper to cause the whole to flow readily from the pencil, in either clearly marked fine strokes or in spread layers, varied in hue by the changing quantity of colour. The oil evaporates quickly, and the vessel is ready for the muffle for the final baking; the carbon is dissipated by the heat, and the vitrification of the flux softens the part of the glaze on which it is traced, by which the metallic calcs become partially fused together. Excess of oil in the working prevents the close flow of the colour in baking, and the design is therefore meagre and imperfect in execution and brilliance.

Most metallic colours on porcelain exhibit all their beauty and brilliance when drawn out of the muffle, the greater number of articles requiring enamel-baking only *once*. As every layer of colour, however, can only have the flux vitrified and the metallic calcs fixed, some require to be *twice* in the muffle, and the finest specimens, which have groups of flowers and choice landscapes with figures, require several repetitions to give the different tints the desired beauty and brilliance.

The *grounds* are formed by a very even layer of linseed oil, red lead, and turpentine boiled two hours, and on which the impalpable powder of colour is evenly dusted by a lock of soft cotton wool.

Gilding.

(669.) The gold calc is ground very fine with a glass muller on a glass palette with oil of turpentine, the more readily to flow, as with a fine hair pencil the design is traced on the very clean surface of the glazed porcelain. Those vessels which have their edges or other parts decorated with a circular line are placed on a *whirler*, and the artist keeps his arm steady on a rest, as the hand holds the pencil to the proper part of the vessel. This implement consists of a pillar and claw resembling a tea table, but the pillar is bored deep, and the upper end has an iron hoop and a thumbscrew to receive and regulate the depth of an iron bar, on whose upper end, placed in a socket, revolves the circular head of wood two inches

Mechanical Processes.

Manufactures

thick and twelve diameter. The workman fixes the proper height of the head, places the claws so that his feet preserve the whole steady, and then, while with one hand he gives motion to the head, with the other he applies the gold (or colour) in very fine or broad lines as required.

The process of baking the gilded ware separates the oxygen of the metal, and leaves the gold in its metallic state, but in appearance of a dull brown colour like tarnished brass; therefore, to be recovered, and to secure the full effect of its beauty and usual brilliancy on those parts of the porcelain which are thus ornamented, the manipulation of burnishing with agate, bloodstone, or other polishing substances, is effected chiefly by young females with great care, because the baking may have been too soon concluded, and the gold may in consequence *chip off*, separate in thin flakes, or it may have been too intense, and prevent the proper lustre of the metal. In proceeding, the article is handled only by a cloth, and after slightly touching a part of the gold with a little white lead and water, the burnisher is applied, very quickly moved over each part, always in one and the same direction, to avoid *scratches* by crossing, and when the bright vivid lustre is raised, the vessel is wrapped in tissue paper.

Leaf-gilding, for the least valuable porcelain, is applying a warm size of half a pint of pure linseed oil, and half an ounce each of gums arabic and benjamin, and acetate of lead well boiled. This is laid very even on the edge of the ware, the vessel is heated a little, and the strips of leaf gold are applied, and adhere as the size cools.

Lustreing.

Lustreing.

(670.) Brushes of badger's hair of different breadths are used to apply to the glaze of the vessels the acidulous solution of metals. When a design is to appear free from lustre, a correct sketch is traced with lamp-black and water, and is well dried; and on some vessels are seen sketches with a strong solution of metallic oxide, over which, as well as all the other parts, is brushed, while the vessel is extremely hot, the lustre solution in a properly fluid state. When the lustre has been baked the metallic oxides have parted with their oxygen, but the metals have diminished brilliancy. The lamp-black is brushed off and the pattern is fully exhibited.

The *baking* of enamel, gilded, and lustre wares, is in an enamelling kiln, in form inside similar to a Chemist's muffle, but varying in size from six to twelve feet long, three to five feet wide, and three to five high. The vessels are carefully placed so as not to touch each other where any of the ornamental work is executed, and on props are placed flat earthen bats or iron gratings, so that the muffle has several tiers of vessels; the whole is secluded from any injurious vapours, and the process is from seven to ten hours. Trial beads are used in this process as in the others; but often the fireman ascertains the progressive vitrescence of the enamel colours, and determines when they are sufficiently baked upon the ware, by a small piece of dry wood cast in through a hole in the clammings, and its white flame during combustion exhibits the true tint of all the colours, not to be discerned on the red ware alone. See fig. 20.

The *gold lustre* is not difficult to make, yet care is requisite. Make a *balsam of sulphur* of best oil of turpentine 86, flowers of sulphur 14, in an earthen jug

gently heated not less than one hour; cool, decant the liquid, and to 60 parts add 40 more of oil. Over a slow fire again heat the liquid, and add to it gold solution 95, tin solution 5, by dropping in while carefully stirring it. Or,

On a plate or tile mix gold precipitate (above) with fat oil; heat gently, and when arrived at a liquid state add oil 25 parts, lower the heat and add turpentine 75 parts. (*Solid lustre*.)

The *silver lustre* is differently prepared. In aqua regia dissolve platinum to saturation, gently heat the acids, and gradually add to solution 25, spirits of tar 75; the nitro-muriatic acid evolves, leaving the platinum in the tar, which is evaporated for use.

Pipemaking.

(671.) This may be considered as a branch of the general Art of Pottery, although a distinct one, which is not so much dependent on locality as that described in the preceding pages. The clay used for the manufacture of these articles is found in different parts of England, but it is mostly obtained from the Island of Purbeck in Dorsetshire. Previously to being used, it must be purified from all extraneous matter, and reduced to the proper degree of tenacity, in lumps of about eighty or a hundred pounds' weight. From these, the pipemaker cuts off, from time to time, small pieces each of about the quantity to form one pipe; these are well kneaded, and afterwards rolled out on a board or table to nearly the size and form of the pipe, leaving a bulb at the end for the formation of the bowl. In this operation a skilful workman will roll the material into pieces of precisely the size and length required for the sort of pipes in hand. In this state the piece of rolled clay is placed in a mould, and all extra portions of it are cut away. It is then left to become a little hardened by drying; and when in a proper state, the stem is bored by introducing into it an iron or wire instrument furnished with a handle the full length of the stem. This operation calls for some address, and requires long practice. In performing it, the roll is taken between the fingers, which follow the end of the needle in its course through the whole length of the stem, a small enlargement being formed near the end, which is perceptible to the touch of the finger outside, and thus becomes a guide for its direction, which ought to be as nearly as possible in the axis of the pipe. This being done, the stem is next placed in a copper mould, divided into two parts, as shown in plate xlix. fig. 3. When intended to be used, the whole interior surface of both sections is slightly touched with a brush containing a little very limpid oil, that the stem may afterwards be delivered from it without difficulty. The roll of clay being placed in one section of the mould, the other is accurately fitted to it by means of marks previously made. The mould is then submitted to the action of a small iron press, by which the two halves are forced together, and all the exterior ornaments, &c., are impressed upon the clay.

It now remains to fashion the bowl. This is, in part, effected by the fore finger, and more perfectly afterwards by means of a stamp or form attached to the mould, and which, by the action of a lever, (acting somewhat like a patten-maker's knife,) is pressed within the hollow made by the finger for the purpose. The bore of the stem is then continued into the bowl, by pushing the instrument above-mentioned for boring the shank up to

Mechanical Processes.

Forming the bowl.

Manufac-
tures.

its handle; any superfluous clay is then cut away, and the pipe is smoothed by means of an iron or copper blade.

The pipes, as they are thus successively formed, are arranged upon a board; in order to their being further dried, and when they have acquired a certain consistency, any roughness which may appear is removed, and the bowl is rendered round and of shapely contour. They are then placed a second time in the mould, and all imperfections of shape are finally remedied. They are now left until sufficiently hardened to receive the last polish, which is given by rubbing them with flints bored with holes, some of which are of the same diameter as the stem, while others will admit the head of the pipe; and sometimes after this the ornaments are retouched with a tool. The needle is then withdrawn, and it only remains to harden the clay in the furnace or kiln.

The above description appears rather long, and the operation tedious. It is, however, by practice, performed with great expedition; at the same time it must be understood that some of the finishing processes are not bestowed upon any but the superior kind of articles. In common pipes many of the latter operations are omitted.

(674.) *Pipemaker's furnace*.—This is represented in plate xlix. fig. 4, 5; its peculiarity consists in admitting the heat to the pipes, while the flame, smoke, &c., which would soil the articles, are excluded. The crucible or seggar is of a cylindrical figure, terminated at the top by a hemisphere; it is placed over the fire-place *b*, inclosed within a lining of fire bricks *c*, and surrounded by an outer case of brickwork *d*. Between the lining *c* and the seggar is a space of about four inches all round, in which the flame from the fire-place circulates without interruption, except what arises from the numerous supports, which are necessary to sustain the seggar in its proper position; but as these are always placed edge-wise to the flame, and are very thin, they cause but little obstruction to its action.

These supports are twelve ribs between the seggars and the lining, which form the same number of flues, as shown by the dotted lines. The ribs are perforated with occasional apertures, to connect one flue with the adjacent one; but the principal bearing of the seggar is taken from five piers formed of bricks, projecting one over the other. One of these piers is placed at the back of the fire-place, and the other four at the sides, projecting at the top nearly into the centre of the fire-room, so as to support and strengthen the bottom of the seggar, which rests upon these piers; the spaces between which form the mouths or commencements of the flues, all these uniting in the dome *g* of the fire-brick linings, and this has a circular opening through it, leading into the chimney *h*.

The lining *c*, *d* of the seggar is open on one side, to form the door at which the pipes are taken in and out of the furnace; the opening is permanently closed as high as *k*, by an iron plate plastered with fire clay; above this the space is left open, and only closed when the furnace is burning, by temporary brickwork: when this is removed, the furnace can be filled or emptied through the opening. For this purpose the seggar has a similar opening in its side; and when the furnace is burning and the aperture is closed, the workman first spreads a layer of clay round the edge of the opening; he then sticks the stem of broken pipes across from one side to the other, and plasters the interstices with clay,

VOL. VII.

in a manner exactly similar to the lath and plaster used in building. The whole of the seggar is made in this manner; the bottom is composed of a great number of fragments of pipes radiating to the centre; these are coated with a layer of clay at the circumference, a number of the bowls of broken pipes are inserted into the clay, then other fragments are placed upright, to form the sides of the seggar. The ribs round the outside, which form the flues, are constructed in the same manner, as is also the dome *g* of the fire-brick lining; by this means the seggar is made very strong, but at the same time so thin, as to require but little clay to construct it, and is less liable to split by the heat, than a vessel formed of thicker materials. This method might be advantageously applied to other cases, where a very thin vessel or lining is required for a furnace.

The pipes which are to be baked are arranged within the seggar, the bowls resting against the circumference, and the other ends supported upon circular pieces of clay *h*, which are set up in the centre for that purpose. Six small ribs are made to project inward all round the crucible at the proper height, to support the different ranges of pipes without having so many resting upon each other, so as to endanger their being crushed by the weight. By this mode of arrangement the furnace is made to contain fifty gross, or 7,200 pipes.

These require from seven to nine hours to be burned: the heat is at first brought on gently, and afterwards increased to the full intensity required for baking this species of pottery. The fire is regulated by a simple kind of damper applied over the aperture in the dome *g* of the fire-brick lining. This is a mixture of horse-dung, sand, and pipe-clay well worked together, and spread in thin layers upon coarse brown paper. A sheet of this being laid over the pole in the dome, so as to cover more or less of it, will give the means of increasing or diminishing the draught, and, consequently, the heat of the furnace.

Glass Works.

(675.) Glass, if not an article of indispensable utility to mankind, is one which contributes largely to the comforts and elegancies of civilized life, and to the prosecution of scientific research. What substitute could we find for the glass which forms our windows, which while it admits almost without diminution the light and warmth of the sun, and allows us to see every thing within and without our houses with distinctness and facility, screens us from the effects of wind, rain, and tempest? And what can be conceived so beautifully ornamental as the rich services of glass we sometimes see, the splendid mirrors, chandeliers, and other decorative articles? In Science, Astronomy is altogether indebted to glass for its present accuracy and perfection, as is also Navigation, and the wonders displayed by the microscope would probably have ever remained hidden from human sight but for the aid of this extraordinary substance. Its manufacture, likewise, considered merely as a Mechanical Art, is extremely interesting, and will, therefore, call for more than usual detail; and its history, although it extends to very high antiquity, and is in its early part somewhat obscure, must also be attempted. For the latter we avail ourselves of a very neat and concise sketch published by Mr. Pellatt, of the firm of Pellatt and Green, whose works are scientifically conducted on a scale of considerable magnitude.

History of
glass.

Of the Art
of glass-
making
known to
the Eryp-
tians.

Glass-
houses of
Alexandria
celebrated.

(676.) *History of Glass.*—The period when the Art of making glass was first discovered is certainly not known, but as it is scarcely possible to excite a fire of sufficient heat for metallurgic operations, without vitrifying part of the bricks or stones of the furnace, (a circumstance which would very naturally suggest the idea of glass-making,) it is probable that this Art is as old as that of working metals, which we have seen was anterior to any existing authentic records.

Glasshouses were at a very early period established at Tyre. Pliny states, that some merchants being driven by a storm at sea to the mouth of the river Belus, were obliged, during the time they were detained there, to dress their victuals by kindling a fire on the sand, where the herb kali grew in great abundance, and that the salts of this plant, on its being reduced to ashes, incorporated with the sand or with stones fit for vitrification, and thus produced glass. However this may have been, the sand which lay for about half a mile round the mouth of the river was peculiarly well adapted to the making of glass, while the extensive range of the Tyrian and Carthaginian commerce afforded an ample vent for the productions of the furnace.

The Art of glass-making was certainly known to the Egyptians, although there exist but few specimens of antiquity to prove the fact. Most writers have erroneously referred to the beads which ornament some of the mummies as satisfactory evidence on this head; but these are not composed of glass, but of burned clay or earthenware glazed, being of a substance precisely similar to the numerous small images of mummies, beetles, and other figures. There can, however, be but little doubt that the Egyptians were well acquainted with the materials for making glass, as well as with the chemical properties of the metallic oxides for covering it; since among the Tombs at Thebes have lately been discovered small solid pieces of glass of a turquois colour which exactly resemble, and perhaps were used for the glazing of the beads and figures of earthenware.

Fragments of white, yellow, and green glass, have likewise been found, but these may possibly have been made by the Greeks or Romans, who successively conquered Egypt, or they may have been procured from neighbouring or distant nations. Some of these fragments are flat, and of a circular form, resembling a coin nearly entire, and of an amber colour, having a well executed figure impressed upon them in bas-relief; others are of a green hue, with Arabic characters. The former are of the size of a sixpence, the latter as large as a half-crown piece.

It appears that the glass-houses of Alexandria were celebrated among the Ancients for the skill and ingenuity of their workmen, and from these the Romans, who did not acquire a knowledge of the Art till a later period, procured all their glass-ware. Strabo relates, that a glass-maker of Alexandria informed him, that an earth was found in Egypt without which the valuable coloured glass could not be made; and it is stated by Pliny, that in the reign of Tiberius, a Roman artist had his house demolished for making glass malleable; and that, in consequence of this discovery, glass came into such general use as to supersede cups of gold and silver, and the glass-makers became so important, that a street was assigned them in the first region of the City.

The Chinese also are known to have possessed considerable skill in this Art; M. Abel Rimusat states, that

the imitation of the precious stone Yeschm was so excellent, that it was impossible to distinguish the artificial from the real. This description of glass-ware was manufactured by the Chinese into vases of various forms, which were procured from them by the Arabians. Some were of a clear transparent white, extremely brilliant, and as pure as the precious stone; and others, of a beautiful blue, they imitated equally pure. In Egypt and Syria no difference was known between the real and the artificial Yeschm: the latter being of the same form, thickness, and specific gravity as the former. It is indeed asserted that in Cairo, and other parts, the artificial vases were as highly valued as those of the real Yeschm, and that enormous prices were given for them. The Chinese have also equally well imitated the Justone, which was too costly for persons of a moderate fortune. It is a coloured glass of rich appearance and greenish tint, and of such hardness and weight that it very frequently surpasses the real Ju. Small vases, figures, and almost every description of ornaments that are sculptured in the real stone, were made in this description of glass. A specimen of this imitation may be seen at the British Museum; it is of a bluish-white, resembling enamel, of an octangular figure, and about the size of a snuff-box; it is extremely hard, and, in proportion to its size, of an astonishing weight.

A most singular Art of forming pictures with coloured glass seems to have been practised by the Ancients, which consisted in laying together fibres of glass of various colours, fitted to each other with the utmost exactness, so that a section across the fibres represented the object to be painted, and then cementing them into a homogeneous mass. In some specimens of this Art which were discovered about the middle of the last century, the painting has on both sides a granular appearance, and seems to have been formed in the manner of mosaic work, but the pieces are so accurately united, that not even with the aid of a powerful magnifying glass can the junctures be discovered. One plate, described by Winkelmann, exhibits a duck of various colours, the outlines of which are sharp and well defined, the colours pure and vivid, and a brilliant effect has been obtained by the artist having employed in some parts an opaque, and in others a transparent glass. The picture appears to be continued throughout the whole thickness of the specimen, as the reverse corresponds in the minutest points to the face, so that, were it to be cut transversely, the same picture of the duck would be found exhibited in every section. It is conjectured that this curious process was the first attempt of the Ancients to preserve colours by fusing them into the internal part of glass, which was, however, but partially done, as the surfaces have not been preserved from the action of the atmosphere.

(677.) The subterranean ruins of Herculaneum afforded many specimens of the glass-manufacture of the Ancients: a great variety of phials and bottles were found, and these were chiefly of an elongate shape, composed of glass of unequal thickness, of a green colour, and much heavier than common glass; of these the four large cinerary urns in the British Museum are very fine specimens. They are of an elegant round figure with covers, and two double handles, the formation of which must convince persons capable of appreciating the difficulties which even the modern glass-maker would have in executing similar handles, that the Ancients were well acquainted with the Art of making round glass vessels, although their know-

ledge appears to have been extremely limited, as respects the manufacture of square vessels, and more particularly of oval, octagonal, or pentagonal forms. Among a great number of lachrymatories and various other vessels in the British Museum, there is a small square bottle with a handle, the rudeness of which sufficiently bears out this opinion.

Portland vase.

(678.) The most celebrated antique vase is that which was during more than two centuries the principal ornament of the Barberini Palace, and which is now known by the name of the Portland vase. It was found about the middle of the XVIth Century inclosed in a marble sarcophagus within a sepulchral chamber under Monte del Grano, two miles and a half from Rome, supposed to be the Tomb of Alexander Severus, who died in the year 235. It is ornamented with white opaque figures in bas-relief upon a dark-blue transparent ground, the subject of which has not hitherto received a satisfactory elucidation; but the design, and more particularly the execution, are truly admirable. The whole of the blue ground, or at least the part below the handles, must have been originally covered with white enamel, out of which the figures have been sculptured in the style of a cameo, with most astonishing skill and labour. This beautiful vase is sufficient to prove that the manufacture of glass was carried to a state of high perfection by the Ancients.

Venice during a long period excelled all Europe in the fineness of its glass. Judging from the curious specimens to be seen in this Country, the Venetian glass-blowers must have been artists of considerable skill; and the Bohemians were also formerly very celebrated for their extensive glass-works. They invented a curious method of ornamenting glass-ware, which has since become well known, and was at one time in much repute in this Country; this consisted in inclosing in the stems of wine-glasses and goblets white and coloured opaque enamel tubes, which they twisted in white transparent glass.

First knowledge of glass-making in Britain.

(679.) Glass-making in Britain is supposed to be of very ancient date; and, if the opinion of Pennant be well founded, of a date prior to the Roman conquest. The Art of manufacturing glass, as beads and amulets, was certainly long known to the Druids, as rings termed the *glain neidyr* or Druid glass rings are very frequently found near Aberfraw Palace. The glass amulets are about half as wide as our finger rings, but much thicker; they are usually of a green colour, but some are blue, and others curiously variegated with waves of blue, red, and white. They are said to have been used by the Druids as a charm to impose upon the vulgar.

Window glass.

It is very uncertain when glass was first employed for the transmission of light and other optical purposes, or how long any of the nations of Europe have enjoyed the benefit of glass windows. One of our oldest English Historians, Bede, tells us that in the year 674 the Abbot Benedict sent for artists from abroad to glaze the Church and Monastery of Weremouth in the County of Durham.

Notwithstanding the interest which so important an application of glass was likely to occasion, it is probable that glazed windows were not common in these kingdoms till several centuries after the period above-mentioned. Dr. Henry says, that although the Art of glass-making was introduced in the VIIth Century, yet it was afterwards so much neglected, that no private house had glass windows till after the conclusion of the Xth Century. Before this period, the windows of houses, and

even of Cathedral churches, admitted the light through fine linen cloths or lattices of wood.

Mechanical Processes.

The first glass-houses of any importance established in England, were those at Crutched Friars, and in the Strand, London, about the middle of the XVIth Century. The Art was afterwards encouraged by King James I. and Charles I., both of whom prohibited the importation of all foreign glass, excepting that of the most inferior kinds. The former of these Monarchs, as an expedient to raise money without the aid of Parliament, granted to Sir Robert Mansel an exclusive patent for making glass, which was afforded him in consideration of his having established the use of pit-coal for wood in its manufacture. He was also allowed, on the same ground, the exclusive privilege of importing drinking vessels, and every other article of glass from Italy, which could be made of a finer quality than had at that time been produced in England.

The second Duke of Buckingham has the merit of improving the manufacture of British glass by bringing over several workmen from Venice: he established a considerable manufactory for making plate glass at Lambeth about the year 1670.

During this interval, glass-making had made considerable progress in France. So early as the commencement of the XIVth Century, the French Government had encouraged this manufacture, by ordering that gentlemen or the sons of nobility might exercise the trade without derogating from their rank; but no great advance was made until the Minister Colbert, by a fortunate event, was enabled to lay the foundation of a manufactory upon the most improved principles.

Certain French artists, established at Venice, found means to obtain at Murano an exact knowledge of the processes employed in the fabrication of plate glass, and they returned to France with the hope of enriching their land with that splendid branch of Art and Commerce. The Minister received them graciously, and having empowered them to select such a situation as they might deem best suited to their undertaking, they established themselves, in the year 1665, at Tourlaville, near Cherbourg. This Company afterwards obtained a patent for making plate glass, and an advance of 12,000 livres for four years was granted them for this purpose by the French Government.

In the year 1688, Abram Theuart, an ingenious manufacturer, made a proposal to the Court for casting glass mirrors, and engaged that they should be of a larger size than any that had been before made. This individual likewise obtained a patent, to continue for thirty years; and the first plates which he cast were made at Paris, and were of the extraordinary dimensions of 84 inches by 50 inches, a size which surprised all the artists of that day. Notwithstanding this success, not more than three years elapsed before the proprietors found it expedient to move their establishment to St. Gobin, in the department of the Aisne, and there they laid the foundation of a manufactory which soon became, and continues to remain, more extensive than any in Europe.

To return again to England, we find the Art advancing with the same, and even a greater degree of rapidity. In the year 1773, a respectable Body of gentlemen obtained a Royal Charter of incorporation, the privileges of which were confirmed to them by Act of Parliament, under the title of "The Governor and Company of British Cast Plate Glass Manufacturers."

Manufac-
tures.

They subscribed a capital or joint stock of eighty shares, of £500 each, and constructed works of considerable extent at Ravenhead, near Prescot, in Lancashire, which still rank among the most important glass-works in this Country.

The Art of glass-making, having been thus patronized by the Nobility and Gentry of the Country, soon made rapid progress, and the attention of scientific men being directed to this subject, great improvements and facilities were introduced in the manufacture; and it may

now be said that we equal, if not excel, those Countries which were formerly our instructors, both in the beauty of the material, and in the variety and elegance of the various utensils into which it is manufactured. The present extent of this Art will be seen from the following Table, giving the quantities of different kinds of glass which have been charged with duty, and the net produce thereof in each year from 1820 to 1831.

Mechanical
Processes.

Years.	Flint Glass.	Fluxed Materials for Flint Glass.	Plate Glass.	Crown Glass.	Broad Glass.	Green Glass.	Total Produce of Duties.

On the Ingredients employed in the Composition of Glass.

Materials
employed.

(680.) Glass is produced by fusing silica with a due proportion of alkali, which acts as a flux to the silica, and renders the whole transparent. Besides these two ingredients, which are absolutely essential to the composition of glass, the following accessory substances are employed, which, by their chemical action, give peculiar properties to the different kinds of glass; viz. borax, carbonate of lime, oxide of lead, oxide of manganese, white oxide of arsenic, and nitre.

The silicious material most commonly used in this Country for the manufacturing of glass is sea sand, which is well known to consist chiefly of quartz; it has the advantage of being naturally divided into grains, sufficiently small to be used without any other preparation than that of washing. The finest sand is said to come from near Lynn, on the coast of Norfolk, and from the Western extremity of the Isle of Wight. Another equally pure kind of silex is the common black flint, which is prepared by heating it red hot and plunging it into cold water, which splits it in every direction, and renders it so brittle that it can be ground in mills without much difficulty. This kind of silex is, however, more commonly used in pottery than in glass-making.

Alkali.

The alkali used in this manufacture is either soda or potash, each being apparently equally well fitted for the purpose. It is preferred in the state of the carbonate, although the carbonic acid is drawn off by the heat of the process; the glass being a compound of silex with pure alkali, and not with the carbonate. For fine flint glass the best pearl-ashes, purified by solution and evaporation to dryness, are employed, but the inferior glasses are made with the coarser alkalies, with barilla, where this alkali is cheap, with common wood-ashes, and

very largely with kelp. Although these last-mentioned alkalies contain many impurities it does not prevent their dissolving the silex into a very good and perfect glass, for the impurities partly consist of neutral salts and partly of lime and other earths, all of which assist in the vitrification. Glass made from these alkalies has always more or less of a green tinge, owing to a portion of iron contained in them, as may be observed in the common bottle glass.

Borax is very important in the manufacture of the finer sorts of glass, from its powerful action as a flux; but it is not used in the common kinds, on account of its high price. Borax is a compound of soda and boracic acid; it is found native in several parts of the world, but is exported into this Country from the East Indies, under the name *tinzel*, which is in a very impure state, and has to be prepared for use by calcination and solution.

Borax.

Lime is employed in the form of chalk as a flux; it is also beneficial in facilitating the operations of the workmen in fashioning glass, and it has the property of diminishing its liability to crack on exposure to sudden and great variations of temperature. Lime is used in small proportions in the glass pots, for the escape of the carbonic acid from the chalk during the fusion causes the materials to swell to an inconvenient degree, and also if the lime is in excess it acts very powerfully on the sides of the pots.

Lime.

In making plate glass quicklime is very commonly employed; but it is necessary that it should be of the very best quality. The limestone brought from Gibraltar as ballast is found to produce much better lime for the purpose than the chalk in the neighbourhood of London; but it is said that the best lime for the glass business is that of St. Vincent's rock, near Bristol.

Two kinds of oxide of lead are used in glass-making viz. litharge and minium. Litharge will melt by lead.

Oxides of

Manufac-
tures.

itself into a very dense, clear, transparent glass, remarkably soft and unctuous to the touch, fusible at a very low red heat, and when melted acting so powerfully on all earthen vessels as to run through the common porous crucibles in a very short time, almost like liquor through a sieve, vitrifying and corroding the bottom of the crucible in its passage. Litharge is therefore a most powerful flux to all earthy mixtures, and it imparts to the glass the valuable qualities of greater density and greater power of refracting rays of light, and of bearing sudden changes from heat to cold without being so liable to crack; it gives also greater tenacity when red hot, and therefore is easier to work.

(681.) Most of the finer glasses contain a considerable quantity of this oxide, particularly the London flint glass, which is used for the purposes of the table, for lustres and other ornamental works, for artificial gems, for optical and a variety of other purposes. Glass containing much lead has, however, the defect of being extremely soft, so as to be readily scratched and injured by any hard body which rubs against it. It is also extremely fusible, so that thin tubes of it will bend with ease in the flame of a candle, and will sink down to a shapeless mass at a very moderate heat.

Glass for
optical pur-
poses.

For optical purposes another great inconvenience attending the use of lead is, that it does not become sufficiently intimately united with the other components for the whole mass to assume a uniform density. It will always happen that the glass at the bottom of the pot contains a larger proportion of litharge than that above. This inequality subsists throughout, so that every stratum of the melted mass is of intermediate density between the stratum above and that below, which is irregular refraction in the glass when wrought; and as for optical purposes the perfectly uniform density of the material is of the greatest importance, this defect is very detrimental to the use of flint glass. The difficulty of obtaining a piece of flint glass sufficiently large for the object of a large telescope, and at the same time perfectly pure, is so great, that as large a sum as £1000 has been given for one piece of glass. Various attempts have in consequence been made to obtain a glass which should have sufficient refraction, and yet not be liable to these defects, and the Royal Society undertook an extensive set of experiments, which were placed under the direction of Dr. Faraday, a Report of which will be found in the *Philosophical Transactions* for 1830.

Black oxide
of manga-
nese.

(682.) The black oxide of manganese has been used for many years in the manufacturing of glass before its precise nature was understood. Its ancient name was glass soap, which denotes its use; namely, that of clearing the glass from any accidental foulness of colour which it might contract from the impurity of the alkali or other materials employed, and particularly from the green tinge, which is owing to the presence of iron.

The circumstances attending the employment of this substance in glass-making are rather of a curious nature. When added in a moderate proportion to any simple glass it imparts a purple hue, and should its quantity be very great the colour is deepened until it becomes nearly black. If, while the mass thus coloured is still in fusion, white arsenic, charcoal, or other carbonaceous matter be added, an effervescence is sure to follow, and the tint becomes gradually more faint until it altogether disappears, and the glass is rendered clear and transparent. Provided the green hue which it is desirable to counteract be considerable, the application

of a small quantity of manganese is not followed by any sensible tinge of purple: but the moment the proportion is more than sufficient for that purpose, the colour immediately appears and must be corrected, which is performed in a very simple manner in the glass-house, by twisting into the pot of melted glass a piece of wood, which, becoming charred by the heat, causes the purple again to vanish; while a slight effervescence, and an escape of numerous bubbles of air, are plainly perceptible.

Mechanical
Processes.

The oxide of manganese is of use from its property of powerfully assisting in the fusion of earthy bodies. It also gives considerable density to glass, but the same disadvantage accompanies its use as already has been noticed with regard to litharge; viz. having from its greater specific gravity a tendency to settle to the bottom of the pot; in addition to which manganese acts injuriously upon the pots, by corroding them at the bottom.

The white oxide of arsenic is another flux used pretty largely in glass-making. This substance being volatile as it approaches the metallic state, it is of advantage to employ nitre to oxygenate it more highly, and make it more fixed. Arsenic is a very powerful flux, and very cheap, but it must be used only in moderation, from the circumstance of its taking a longer time to mix intimately with the glass, and to become perfectly clear, than any other of the additions commonly employed. Glasses in which arsenic is not thoroughly fused have a milky hue, which increases by age when the arsenic is in excess; they have a tendency to become soft, are decomposed, and are therefore unsafe for drinking vessels. The arsenic is constantly volatilizing from the arsenical glass when preparing, until it is intimately united with it, after which it cannot be separated by heat or any common means.

White
oxide of
arsenic.

As arsenic is entirely volatilized when in contact with any carbonaceous matter, it has been made useful in dispersing any substance which may remain in the glass, owing to a defect in the calcination of the alkali or any other cause. When this happens, small lumps of white arsenic are sometimes thrust down to the bottom of the glass pots, and stirred in with the contents; and the arsenic, meeting with the unburned carbon diffused through the glass, carries it off by volatilization, and the glass is left free from the adhering colour, and the greater part of the arsenic which was added. The motion excited throughout the melting glass, by the volatilization of the arsenic, is also thought useful in hastening the complete vitrification of the ingredients.

Nitre is used in destroying any carbonaceous matter in the ingredients with which it should be mixed before fusion. It is also useful in destroying a red purple tinge which is given by manganese.

On the Proportion of Ingredients in different Kinds of Glass.

(683.) There are five distinct kinds of glass at present manufactured.

Proportion
of ingre-
dients in
different
kinds of
glass.

1. Flint or crystal glass.
2. Plate glass or glass of pure soda.
3. Crown glass, the best window glass.
4. Broad glass, a coarse window glass.
5. Bottle or coarse green glass.

Flint glass, so named because the silicious ingredient originally employed was ground flints, is the most bril-

Manufactures.

lial and beautiful vitreous compound with which we are acquainted; and although the quantity manufactured may fall short of some of the other kinds of glass, yet its uses are so much extended and so important as to give it the first rank in this description of manufacture.

The composition commonly employed for it in this Country is as follows:

Purified Lynn sand.....	100 parts
Litharge or red lead.....	60
Purified pearl-ash.....	30

To correct the green colour, a little black oxide of manganese is added, and sometimes nitre and white oxide of arsenic.

Loysel recommends the following composition for crystal, where coal is employed as fuel:

White sand.....	100 parts
Minium.....	80 to 85
Pearl-ash.....	35 to 40
Nitre.....	2 to 3
Oxide of manganese.....	6

Where wood is used for the reduction of the ingredients, and where the crucibles may be left uncovered during the process, a different mixture is preferred. In this, a much smaller proportion of metallic oxide is added, the reason of which M. Loysel states to be that the air, having constant and unimpeded access to the surface of the glass, supplies any deficiency of oxygen, while the process through the direct application of heat is more quickly performed, and the glass is harder and more durable.

Dr. Faraday's glass.

(684.) Dr. Faraday, in his experiments to obtain a glass which should be perfectly homogenous and fit for optical purposes, made use of the following composition:

Nitrate of lead.....	154.14
Silicate of lead.....	24.00
Crystallized boracic acid.....	42.00

These proportions, when heated and submitted to a mutual action on each other, produced 152 parts of glass, containing

Protoxide of lead.....	112
Silica.....	16
Dry boracic acid.....	24
	152

The nitrate of lead was procured from litharge, by first washing, in order to separate the carbonaceous and ferruginous particles, and then dissolving it in dilute nitric acid, so as to form a hot saturated solution.

The silica was the common flint glass-maker's sand, from the coast of Norfolk, and the silicate of lead was prepared by mixing two by weight of this sand with one of litharge. The mixture was put into a large Hessian or Cornish crucible, which, being covered over, was placed in a furnace, and raised to a bright red heat for eighteen or twenty-four hours. On taking out the crucible the charge was found somewhat diminished in bulk, and of a porous structure and appearance, like loaf sugar. Before being used, the outside portions were removed and the pure parts carefully pulverised in a clean Wedgwood mortar, and afterwards washed over in water so as to obtain the whole in a fine state of division.

The advantage of silica in this combined state Dr. Faraday states to depend upon the composition of the substance, its comparatively easy pulverisation, and ready fusion with other metals.

This ingenious Philosopher formed a great variety of glasses with different proportions of ingredients, which

varied considerably from each other, although by no means to the extent of the difference between them and common flint glass. The specific gravity is very high in that made with borate of lead, consisting of single proportions; that is, nearly 24 by weight of boracic acid and 112 of oxide of lead: it is often as high as 6.39 or 6.4, being double that of some specimens of flint glass. In that made with the silicated borate of lead, which, in addition to the former qualities, contains 16 parts, or a proportion of silica, the specific gravity is about 5.44, that of ordinary flint glass being 3.290 and Guinaud's, 3.616.

The refractive and dispersive power was found to increase, as might have been expected, with the specific gravity. The power of two kinds, namely, borate of lead, and silicated borate of lead, have been ascertained by Sir John Herschel, and are as follows:

	Bor. Lead.	Sil. Bor. Lead.
Angle of glass prism.....	29° 6'	30° 26'
Refractive index for extreme red rays.....	$\mu = 2.0430$	1.8521
Ditto maximum yellow..	$= 2.0652$	1.8735
Ditto extreme violet.....	$= 2.1223$	1.9135
Dispersive index $= \frac{\delta \mu}{\mu - 1}$...	0.0740	0.0703

These intense powers upon light are not accompanied by any circumstance rendering the glass optically unfit for the compensation of the dispersive powers of crown or plate glass. Three object glasses were constructed for the express purpose of ascertaining this point, and all of them tend to demonstrate that the compensation or correction may be effected with equal if not greater facility than with flint glass.

In point of hardness these glasses differed as much from each other as in any other quality, and, indeed, more so. The borate of lead is very soft, the bi-borate of lead is harder, and the tri-borate equal to flint glass in hardness. The silicated borate of lead is softer than flint glass, but the glass consisting of one proportion of oxide of lead, one of silver, and one and a half of boracic acid, is as hard as ordinary flint glass; at the same time it has a degree of fusibility, colour, and other properties which renders it a very promising variety. The hardness increases with the diminution of the oxide of lead, but the fusibility diminishes in the same proportion; and this is a property which is essential to preserve to a certain degree for the removal of striæ and bubbles.

Many other useful results were deduced by Dr. Faraday from his experiments, which the limited extent of this Essay will not permit us to notice. We, therefore, again refer the reader to the *Philosophical Transactions* for 1830, where a detailed account of the experiments is given.

Plate Glass.

(685.) In the formation of good plate glass, one of the most important considerations is the preparation of the soda, which is the alkali preferred. This is done by decomposing the muriate of soda (common salt) by means of subcarbonate of potash, both salts being in a state of solution assisted by heat. After this, a portion of muriate of potash is separated from the solution by priority of crystallization, when the remaining alkaline solution is boiled down to dryness and reserved for use.

After the alkaline salt has been thus prepared, it is in

Mechanical Processes.

Manufactures.

some measure necessary to analyze it, with a view to ascertain how much real alkali it contains, and, hence, how much sand it will require. When this is known, the calculation is made without any difficulty, for it is found that one pound of pure soda is sufficient for four pounds of sand, to produce a hard compact glass, which cannot be injured by the action of water, or even by the common mineral acids. Thus, if the prepared alkali should contain 40 per cent. of real soda, which is about the usual quantity, the remainder being muriate of potash, carbonic acid, and water, the operator should take 160 pounds of sand to every 100 pounds of such salt. Upon these data Mr. Parkes gives the following proportions of the materials to produce a glass suitable for the best plates.

Lynn sand previously well washed and dried	720 pounds
Alkaline salt prepared as above.	450
Quicklime slacked and sifted	80
Nitre	25
Cullet or broken plate glass.	425
	1700

If the process be well conducted these quantities of different materials will produce one pot of metal, containing 1200 pounds of good plate glass.

Dr. Ure gives for the best proportion of the materials,

Pure sand.	43
Dry subcarbonate of soda. ...	26.25
Pure quicklime	4
Nitre.	1.5
Broken plate glass.	25.0
	100

From which about 20 parts of good plate glass may be run off.

The lime is of considerable use here, adding much to the fusibility of the materials, supplying in this respect the use of litharge in the flint glass; too much lime, however, impairs the colour and solidity of the glass. About one-fifteenth of the whole is as much as can be used with propriety; and some use as little as one-twenty-fourth.

The substances added to destroy the colour are cobalt blue, and manganese. The manganese is in sufficient quantity to impart a slight red tinge, which, when intermixed with the blue of the cobalt and natural yellow of the other materials in proper proportions, is found to neutralize them so that scarcely any definable tint remains.

Crown Glass.

Crown glass.

(686.) The alkali employed for this description of glass is generally kelp, but being an alkali which varies so much in its quality, it is difficult to give any defined proportions for its use. The following are the most common:

Irish kelp dried and ground. .	450 pounds
Lynn sand dried.	325
Slacked and sifted lime	25
	800

In addition to these substances, a quantity of arsenic is very commonly added to facilitate the fusion; and zaffre or the oxide of cobalt, with ground flint, is also used to correct the dingy yellow, which the inferior kind of crown glass naturally acquires, and by thus adding the blue, natural to glass coloured with this oxide, the whole

is converted into a soft green light. The green hue thus given is very slight, and not disagreeable to the eye, and is hardly perceptible unless the light pass through a great thickness of glass, as happens when a piece is held edgewise. The quantity of zaffre necessary for this effect is extremely small, one ounce being sufficient for 1000 pounds, and when the alkali and sand are good none at all is required.

Mechanical Processes.

The Orkney kelp is sometimes preferred for window glass, because it makes it of a better colour than the Western Isle or the Scotch kelp. Mr. Bowles, the celebrated maker of crown glass, at Cock-hill, Radcliffe-highway, London, is said always to have used Spanish barilla instead of kelp, and his glass was generally preferred to that of others.

Broad Glass.

(687.) Broad glass, although employed for the purpose of window glass, is quite a distinct manufacture to that of the crown glass, both with respect to the materials employed and the process of fabrication.

The ingredients are soap-boiler's waste, kelp and sand, in about the proportion of six bushels of the first to three bushels of kelp, and four of sand; but from the great variability of the qualities of these materials there is no absolute rule for the proportions. Loysel has stated, as the result of his own experience, that if coarse sand be used, two pounds of pure alkali must be put to every four pounds of sand, or it will not melt; but if the sand were very fine, one pound of pure soda would be sufficient.

Green Bottle Glass.

(688.) This is the coarsest description, and executed in greater quantities than any other kinds of glass, so much so, that one half of the entire manufacture of this material in Great Britain is of this kind.

It is commonly made of soap-boiler's waste and sand, in various proportions, according to the quality of the materials. Sometimes a portion of kelp is also added, but this is not used in all manufactories. In consequence of the rate of duty being only one-eighth of that levied upon flint, the manufactories are restricted to the use of the commonest kind of sea or river sand, lest the revenue should suffer by the superior quality of the less-burdened ware. This use of so coarse a sand occasions the necessity of the employment of a large portion of alkaline matter, and in this respect increases the charges to the glass-blower. The impurity of the alkali, and the abundance of fluxing materials of an earthy nature, joined to the very high degree of heat at which they are fused, occasion the glass to contain a very small proportion of saline matter, for which reason it is better qualified than flint glass for the recipient of fluids which have any corrosive action; chemical retorts, sublimary vessels, and carboys for containing aquafortis, should for this reason be always made with the common glass, which has this further advantage over the flint that it will bear a much stronger heat without being softened or undergoing any alteration of shape.

Bottle glass is very hard and well vitrified, and is of less specific gravity than other descriptions. The composition employed in France to produce this material, as given by Loysel, is

Common white or yellow sand. . .	100 parts
Coarse kelp.	30

Manufactures.

Lixivated earth of ashes	160
Brush wood or other ashes	30
Brick clay	80

To which is added a quantity of broken glass, generally to the amount of 100 parts.

At Newcastle-upon-Tyne, where the manufacture of bottle glass is much encouraged, by the excessive cheapness of small coal or slacks, the manufacturers employ a mixture of lime and sea sand. The sand is frequently melted with sea water, which, on evaporating, deposits its salt, of which the soda contained is the only alkali employed. When combined with silica and exposed to a high degree of heat, lime appears to be endowed with the property of decomposing common salt; its presence is therefore essential to the success of this operation.

On the Fusion of Glass.

Fusion of glass.

(689.) The operations of the glass-house admit of being divided into two distinct classes; viz. those connected with the fusion or formation of the material itself, and those connected with its manufacture into the various articles for which it is employed. Under the present head we speak simply of those processes necessary to bring the glass into a proper state to be operated upon by the glass-manufacturer.

Fritting.

The first process in glass-making is that of preparing the materials for the glass pots, which is termed fritting, and consists in calcining them to a point of semivitrification, in which they strongly adhere, and begin to become pasty, but are still opaque, and not yet homogeneous. This process is sometimes performed in small furnaces adjoining the glass furnace, and heated by the same fuel after the chief force has been spent upon the glass pots, although generally small furnaces or ovens are constructed for this express purpose.

The uses of this operation are to drive off the moisture from the materials, which might endanger the destruction of the glass pots, and to expel the carbonic acid from the alkalis and chalk, by which the swelling of the materials is prevented.

This calcination has also the further advantage of causing a chemical union to commence between the alkali, silex, and metallic oxides. For if the raw materials were immediately exposed to the intense heat of the glass pots, the alkali would flow like water, and the grosser particles of the sand, and the heavier oxides, would settle to the bottom, leaving the alkali above nearly disengaged, and thereby liable to act on the crucibles; besides which a large portion would be rapidly volatilized to mere waste. The glass materials would thus have an excess of sand from the loss of the alkali, and a portion would remain at the bottom unvitified.

These operations do not apply to the preparations of materials for flint glass, the fusibility of which is much greater than that of any other description, owing to the presence of so large a portion of lead. For this reason, manufacturers of this kind of glass apply the process of calcination to the sand alone, with a view of separating from it all carbonaceous impurities, previously to its admixture with the remaining materials.

When the process of calcination or fritting has continued for a sufficient length of time, which varies from six to twenty, or even to a greater number of hours, depending upon the materials employed, the substance, which is in a softened state, is either made into the form of square cakes, known to the workman by the name of

frit, to be preserved for future use, or thrown at once into the crucibles in the furnace, where the fire has been previously raised to its greatest intensity. As the fritted materials are much more bulky than when fused, the pots receive their full charge by two or three successive portions, the last added being always thoroughly melted down before a fresh charge is thrown in. When the pots are full, the side opening in the furnace, by which the materials are admitted, is closed up (except a small opening for examining the work) until the complete fusion and refining of the materials has taken place.

(690.) As soon as the frit begins to feel the action of the fire in the glass pots, it sinks down into a soft pasty mass, and gradually increases in tenacity until a perfect fusion is effected. It is still, however, opaque at first, owing to the rising of a quantity of white porous scum, known by the name of *sandiver*, or *glass gall*. This substance has engaged a good deal of the attention of scientific men. It appears to be a confused mass, consisting of all the salts contained in common alkalies, which readily melt at a somewhat less heat than glass, and, being naturally very volatile, and having little, if any, affinity for silex, do not unite in the composition. When laded out and cooled, it forms a white crumbly mass, sometimes quite white, and at others brown and foul, and strongly saline, but not very uniform in its composition, being sometimes very bitter, which is probably owing to the sulphate of potash. Glass gall is very volatile in a strong fire, so that it is constantly dispersing from the surface of the glass in a dense vapour, which very powerfully corrodes the top of the crucible in its passage. If the fusion were continued a sufficient length of time, the whole might be dispersed in this way; but it is generally skimmed off with iron ladles, to be sold to the metal refiners, to whom it is very valuable as a flux. Some of the alkali itself is also dissipated by the continuance of the fire, partly before it can unite with the silex, and partly from the glass after vitrification, to which the corrosion of the pots must in some measure be owing; it unites also in some measure with the glass gall, which renders it slightly deliquescent. An abundance of glass gall is one of the greatest inconveniences that a glass-maker can meet with, as it requires a considerable time and a very strong heat before the whole can be dissipated; and if the glass be wrought before it is thoroughly purged of this material, it will be full of bubbles, unsound, and of a cloudy appearance. Glass made from potash is more likely to suffer from this impurity than the soda glasses, being harder and not so thin as the others, and the glass gall does not so readily dissipate in the fire.

There is another heterogeneous substance also called *sandiver*, which sometimes is found at the bottom of the pots, and is taken out when the whole is worked up. The nature of this is very different, from the other, consisting apparently of a vitrified mass of arsenic and other impurities.

As the heat in the furnace is continued, the glass gradually becomes more flexible, dense, and less brittle, the glass gall is at last entirely dissipated, and the vapours which it occasioned are no longer to be perceived. The glass is now full of minute specks and bubbles, which the heat causes to expand and burst at the top, till at last it refines beautifully clear, transparent, and colourless, as may be seen by the samples which are taken out by an iron rod and cooled. This latter part of the process, from the cessation of the

Mechanical Processes.

Manufac-
tures.

vapour of the glass gall, and its thorough removal, to the time when the glass is thoroughly free from bubbles, is called refining.

The fusion of the glass is now complete, but of much too thin a consistence to be wrought; it is therefore required to be cooled down, which is done by stopping the draught of the furnace at that part where the crucible is placed. The furnace is now re-opened by removing the clay already mentioned, and the operations of the glass-blower may be commenced.

When cooled to the heat proper for being wrought, the glass has lost its perfect fluidity, being of a consistent and tenacious mass, soft enough to yield to the slightest external pressure, yet capable of being bent, pulled, and fashioned into all imaginable shapes, without cracking or parting with its tenuity; so that if in this state it be stretched or drawn out it will preserve the form of a solid fibre, constantly decreasing in diameter, and will not separate until reduced to a minute filament. When no longer heated to redness, it becomes rigid, brittle, and transparent. During the whole time employed in working a pot of glass, which varies from five to twenty hours, and is sometimes even longer, its consistence should be maintained as nearly as possible at the same point; and to succeed in this considerable attention on the part of the workmen is required.

Furnaces.

(691.) *Furnaces.*—In consequence of the intense heat employed in the fusion of glass, the construction and materials of the furnace are subjects requiring considerable attention, not only with a view of rendering it capable of giving the requisite heat, but to construct it of such materials as will bear great heat for a length of time without destruction. The chief material, both in the walls of the furnace and in the pots, is clay, which is mixed with a proportion of sand; the relative quantity of the two depending on the quality of the materials. In general, a fine stiff clay will require about two-thirds the quantity of sand to bring it to such a consistence that it will work easily, dry into a compact mass, and resist the action of the fire for a length of time. The addition of too much sand renders it fusible, and liable to vitrify and separate from the walls by the action of the heat for a length of time; it is therefore advisable to use as little sand as possible, consistently with the proper working of the material.

Glass pots.

(692.) *Glass pots.*—Still greater attention is required in selecting the proper materials for the glass pots, as these have to withstand for a considerable length of time, not only the constant action of a fierce fire, but also the solvent power of the glass itself, with the variety of powerful fluxes in full vitrification. The pots, therefore, being made of earth, the material of them must necessarily be gradually dissolving, and hence, besides the property of difficult fusibility, earth of considerable purity is required; so that a small admixture of it with the glass may not injure its quality.

They are made commonly with five parts of the best Stourbridge fine clay, and one part of old broken crucibles, ground to powder for that purpose. Great nicety is required in mixing these materials, and in working them together, in order that every particle of air may be driven out, the presence of which would by its expansion in the furnace endanger the breaking of the pots. The clay is kneaded by the workmen, who tread it with their naked feet, turning it over from time to time, so that every part is equally acted upon. Attempts have

been made to effect this by Machinery, but they appear not to have been attended with success.

Mechanical
Processes.

When the material is sufficiently worked, it is formed into the pots, and left for several months, in order that the clay may be dried equally throughout the substance: and any small fissures, formed by unequal shrinking of the material, closed up by gently beating with a mallet. They are afterwards heated very gradually to a red heat, in a small oven made for the purpose; and, being kept for a considerable time, are removed while still hot to the furnace, and soldered down in their place by fine clay. A still further shrinking takes place in the glass furnace, for which reason they are left to stand empty for a few days before the gross materials are admitted. They last upon an average about a year, and generally have to be changed two or three times during the continuance of the furnace.

The manner of arranging the pots in the furnace will be understood from fig. 1 and 2, pl. 1. which represent a section and ground plan of an eight-pot furnace for flint glass. It consists of two parts, A A, B B, one within the other, of which the interior one is flat, and the exterior of considerable altitude, terminating in a high chimney: the only connection between the domes is by the flues G G, which are situated one on each side of the crucibles, so that they receive the whole body of the flame as it passes from the fire-place to the exterior dome, and thence to the chimney. The shape of the pots C C, &c. is peculiar, being of a circular figure at bottom, and furnished with a projecting part or spout at the top. They are situated at equal distances round the furnace, between the pillars or piers E E, &c., which support the exterior dome, and in such a position that while the body of the crucible is within side, and exposed to the most intense heat of the flame, the front or projecting part is level with the exterior of the furnace. By this means, while the contents of the crucibles are accessible to the workman from the outside, they are shut out from the interior of the furnace and immediate action of the flames, which would be very liable, from occasionally parts falling in, to injure the quality of the glass. The fire-place is supplied with fuel by the openings a a, in two of the piers, which are however so weakened by it that additional pillars are necessary at that part for the support of the exterior dome.

Construction of a
glass furnace.
Pl. 1.
Fig. 1, 2.

For the construction of furnaces for crown and other kinds of glass which are similar in principle to the above, although their shape is in some measure varied, we must refer the reader to Loysel's *Art de la Verrierie*, where a particular account of these furnaces is given; we proceed to describe the manipulations of the manufacture.

Manufacture of Flint Glass.

(693.) The aid which the improvements in Machinery have afforded the greater proportion of our manufactures has not at present been extended to that of glass, and in this respect it may fall short in interest if compared with some others; there is, however, a degree of skill and sleight-of-hand displayed by the workman in the different processes in forming the great variety of utensils made of this material, which is certainly not excelled in any other Manufacture, and which universally excites the astonishment and admiration of those who behold them.

Flint-glass
manufac-
ture.

In consequence of the superior brilliancy of flint glass

Manufac-
tures.

in comparison with the other kinds, it is most commonly employed for all the ornamental utensils which adorn the tables of the wealthy, for which purposes it possesses an additional advantageous property, *i. e.* of possessing when at the working heat a degree of tenacity and ductility not to be found in any substance in nature.

Although the shapes given to glass vessels are so very varied and numerous, they are produced by a few simple instruments; and almost every article, of whatever figure it may be, is shaped out of a hollow globe formed by blowing.

Glass-blow-
ing.

(694.) The most useful implement in this process is an iron tube, about four or five feet long. To form a globe this tube is dipped into the pot containing the glass at the working heat, and turned about until a sufficient quantity adheres to it for the purpose intended. It is then held near the ground, by which the glass lengthens by its own weight, and assumes the shape of a pear. The workman then blows strongly through the tube, and his breath penetrating the centre of the red hot mass extends it into a hollow globe of uniform thickness. It must be blown out as large as intended, and the force of the breath kept upon it for a few seconds, till it stiffens by cooling, otherwise it would sink again by the pressure of the external air. This operation produces a hollow globe, adhering to the neck of the iron rod, out of which an immense variety of forms may be produced.

Mode of
making
glass drink-
ing utensils,

We cannot here pretend to give an adequate idea of the ease and dexterity with which this beautiful substance is formed from a globe into the numerous shapes given to decanters, wine-glasses, &c. The following description of the mode of making the common tumbler, which is perhaps the most simple table utensil, will however illustrate in some measure the manner in which the manufacture is conducted.

A hollow globe with a short neck being first blown on the iron rod, as above mentioned, it is transferred to a short solid iron rod by an assistant, who dips the end of the rod into a glass pot, and brings it out with a little melted glass adhering to it, which he immediately places at the bottom of the globe at the part directly opposite the neck: to this it firmly unites, so that the globe becomes cemented on this second rod, by means of the melted glass. The workman then wets a small piece of iron with his mouth, and lays it on the neck of the globe, which is still extremely hot, and thus causes it to crack all round in a second or two, so that with a slight pull it comes off, leaving the globe open at the neck, and attached to the second rod on the opposite side. The globe is now again softened by holding it for a few seconds over the mouth of the glass pot, and a portion of it is cut from the open end by a pair of shears, leaving the remainder in the form of a cup. The workman when at work usually sits upon a kind of arm-chair, the arms of which slope forwards, and are covered with a flat, smooth, iron plate; so that by resting the rod on both arms of his seat, and twisting it backwards and forwards, the hot glass at the end is made to revolve like clay in a potter's lathe. The workman takes in his right hand an iron instrument, in some measure resembling a pair of sugar-tongs, being connected at top by a flat elastic spring, but having the prong nearly of a round figure. By this simple instrument he may give the glass while in motion an infinite number of shapes with a degree of facility that can scarcely be conceived by a person who has not witnessed the opera-

tion. If the glass have cooled below the working heat, previous to the final shape and smoothing being completed, it must be again heated by holding it at the mouth of the crucible, and continuing the operation; if not completed by the second heating, it must be re-heated, and so on alternately until the vessel is of the required shape, when it is separated from the iron rod by wetting it at the point of attachment. This last operation leaves that burr or roughness which is seen at the bottom of all glass unless taken off by grinding.

Mechanical
Processes.

Decanters are rather a more complicated piece of workmanship, the shape being given from the globe while it still remains on the iron tube. The flat or upper part of the instrument is used for this purpose, which, by alternately pressing against the glass in the parts required to be flat, and blowing through the tube, the body of the decanter is soon brought to the proposed shape. A workman now brings the iron rod with a piece of melted glass, which he attaches concentrically with the bottom of the decanter; the other workman at the same time applies the cold iron rod moistened with water to the other end, and the glass vessel is by this means almost instantaneously transferred to the iron rod. The decanter has now to be again heated, in order to form the mouth part, which is done by first smoothing the end very truly, by introducing the prong end of the tool, and bringing it into a position nearly at right angles with the axis of the decanter. The rings which are formed on all decanters are still to be added, which is done by the addition of fresh glass. An assistant workman brings an iron rod, provided with the required quantity of melted glass, which he applies at the part where the ring is intended to be made, and the workman at the same time turning the decanter, a ring of melted glass is caused to encircle it, which is made of the required shape by a gauge contained in the inner part of one of the prongs of the above-mentioned tool. In the same way the remaining rings are put on, which being done, the decanter is again introduced into the mouth of a glass pot, and brought up to a considerable heat, in order that the rings may be well fused with the body of the metal. The decanter is now complete, with respect to shape, but is again submitted to the turning operation as it cools, to be rendered smooth and perfectly true in every part.

The manner in which all other round glass vessels are formed is similar to that described above, so that it is unnecessary to enter into any further description of them. Vessels which are not of a round figure cannot, however, be accomplished by these means: it is then necessary to have a mould, in which the glass is placed while it is blown, which causes it to take any impression with the most complete precision.

(695.) *Annealing.*—Another important process is *Annealing*, required before the glass vessel is fit for use, *viz.* that of *annealing*, without which it will always be liable to fly by the least change of heat and cold, by the smallest scratch, or even without any apparent external cause. This process consists in allowing the glass to cool very gradually in a low chamber built for the purpose, near the furnace, which is sufficiently hot at one end to keep the glass in a state approaching to softness, but gradually diminishing in heat towards the further end; so that being introduced at one end, and pushed forward as new articles are brought up, it arrives by degrees at a cooler part of the oven, and finally at the other extremity, where the temperature does not exceed that

Manufac-
tures.

of the surrounding atmosphere, and whence the vessels are removed for use, the disposition to fracture above described being entirely removed, if the operation has been continued for a sufficient length of time, which with common articles is generally about twenty-four hours.

The extreme fragility of unannealed glass is very remarkable and difficult to account for; but is supposed to be owing to the forcible contraction of the outer part by sudden cooling, while the inner portion is still soft and semifluid; so that there is an inequality of strain throughout the fibres, and as glass is extremely elastic as well as brittle, any force which tears asunder a portion of the strained part communicates a strong and sudden impulse over the whole mass. This theory in some measure is borne out by the very interesting experimental toys termed the Bologna phial, and the Rupert's drop. The former is simply a phial, of any form whatever, made of any kind of glass, but much thicker at bottom than at top, which is cooled immediately without annealing. Being made rather stout it will bear a smart blow with a wooden mallet or any blunt instrument, or the concussion of a leaden bullet dropped into it from a considerable height, without injury; but if any sharp body however small, such as a grain of sand or a small piece of a gun flint, be dropped in only from a few inches height, the bottom cracks all round, just above the thickest part, and drops off; and the same effect happens if the bottom be scratched with any hard body. The effect is not always immediate, as the phial will remain sometimes for a few minutes and sometimes for hours, and then suddenly give way.

Bologna
phial.

Rupert's
drop.

The Rupert's drop is simply a small solid lump of glass, poured when red hot into cold water, which causes it to assume a round figure, elongated into a kind of tail. This solid lump will bear very considerable resistance on the rounded end without injury, and is altogether extremely tough; but when the least portion of the thin end is broken off, the whole bursts with a smart explosion, and into a countless number of fragments, as small as fine sand. It is a very common trick, played upon those unacquainted with the toy, to give one in their hand, and then to break off the end, when to their astonishment and alarm a great explosion takes place; but the fragments are so small that no injury is done to the hand, otherwise than a sharp stinging sensation, which, however, from being so totally unexpected, is very frequently magnified by the astonished experimenter into a more serious affair.

The force of the explosion is said to be so great, that if one of these drops be placed in a phial or tall glass filled with water, and the end broken off with a pair of pincers, the vessel will be infallibly broken. The stoutest wine or beer bottle would not be strong enough to withstand the shock.

This very singular effect can only be owing to some permanent and very strong inequality of pressure; for if the drops are heated and allowed to cool of themselves, this property of bursting is entirely lost. The brittleness of the Bologna phial is also removed by again heating and cooling slowly.

Glass
cutting.

(696.) *Cutting glass.*—The glass utensils which contribute so greatly to the embellishment of tables and saloons owe much of their richness and brilliancy to the elaborate manner in which they are cut. The implements employed by the glass-cutter, although of necessity numerous, owing to the great variety of work which

he has to execute, yet partake of the same simplicity which is observable throughout the various processes of this Manufacture.

Mechanical
Processes.

The cutting instruments employed are of a circular figure, and are attached to an axle, which may be made to revolve either by an assistant, or by the power of a steam engine or horse-mill. The workman presses the glass vessel against the wheel, and by that means produces an impression in the glass of a figure, depending upon that of the cutting wheel. The materials employed in the formation of these cutting implements are both wrought and cast iron, Yorkshire stone, and willow wood. Wrought iron is used only for cuttings of such narrow dimensions that they cannot be made by cast iron. Iron wheels are used in the commencement of the operation, with sand, which causes them to cut very rapidly into the glass. They leave the work very rough, so that a great deal of grinding and polishing is afterwards required, and they are for this reason not made use of in executing fine work, the grinding being performed entirely by the Yorkshire stone. Over each wheel a small keg or conical vessel is placed, the opening of which is so situated that a due quantity of water is supplied regularly to it, and when the iron wheel is used, this vessel is furnished with a quantity of sand, and water being admitted into it from another vessel, a regular supply of moistened sand is delivered upon the face of the wheel.

After the glass has been reduced pretty nearly to the required figure by the iron wheel and sand, the former is removed, and a wheel of Yorkshire stone substituted in its place, and by this the asperity and roughness are worn down, and the cutting is reduced to the exact figure required, so that no further process is necessary, except that of polishing. This operation is performed upon wooden wheels, the surfaces of which are covered with pumice or rotten stone, and afterwards with putty powder, to give the high degree of polish requisite for finishing.

(697.) *Glass pressing.*—In consequence of the great amount of labour required to cut glass elaborately, and the consequent expense attending it, several methods of ornamenting as a substitute have been attempted, and although they fall far behind the cut glass in point of brilliancy, yet from their greater cheapness they are very much to be recommended. We refer more particularly to an invention which has recently been the subject of a patent. The pattern is given by placing a quantity of melted glass within an external metallic mould of the required form, and then bringing down an interior one, of the shape and dimensions of the interior of the required utensil, and pressing the melted glass between the two. The two parts of the mould are connected together by means of a hinge, and the upper one is provided with a long handle, which acts as a lever for imparting the requisite pressure. The lower section is composed of two pieces, which, being opened, the glass can be removed from the mould immediately after formation.

Glass press-
ing.

An immense quantity of glass is to be seen in our shops manufactured in this manner, more particularly tumblers: they can always be distinguished from those which have been blown and cut by the bottom being of a regular figure.

(698.) *Watch glass.*—Although the most extensive application of flint glass is in the fabrication of vessels for the table, there are many others of considerable importance to which it is adapted, among which may be

Watch
glasses.

Manufac-
tures.

enumerated watch glasses. They are made from hollow globes about 8 inches in diameter, weighing about 12 ounces. The spheres are then divided into a number of pieces by a workman, who takes the globe in his lap, and with a piece of heated wire or tobacco-pipe traces lines upon it in the places where he desires it to be separated, and immediately after wets it, which causes the glass to divide along the lines traced by the wire with the utmost precision. For tracing, a piece of tobacco-pipe is preferred, because it retains for a longer time a sufficient degree of heat.

The pieces into which the globe is divided have of course many angular irregularities, which are removed by a pair of scissors. Before the watch glasses are completed it is yet necessary to give each segment an additional degree of convexity, which is done by first heating, in order to render them soft, and then, by an appropriate instrument, pressing in the edges of the glass towards the centre, which is by this means made to rise in corresponding proportion. The edges are then ground evenly off, and the watch glasses are ready for sale.

Lunette
glass.

Lunette glasses are made from a pear-shaped figure, having the larger end farthest from the extremity of the rod, of the size required for the watch glass, and the requisite flatness is given by pressing the end while soft upon any smooth level surface. These are necessarily much higher in price than the watch glasses commonly used; both because they are made to contain a greater weight of glass, and because only one being cut from each pear-like figure the labour expended in the Manufacture is proportionally greater.

Manufacture of Flint Glass for Optical Purposes.

Manufac-
ture of flint
glass for
optical pur-
poses.

(699.) The general transparency, hardness, unchangeable nature, and varied refractive and dispersive powers, Dr. Harding remarks in his *Memoir* on this subject, render glass a most important agent in the hands of the Philosopher engaged in investigating the nature and properties of Light, but when he desires to apply it according to the laws he has discovered in the construction of perfect instruments, and especially of the achromatic telescope, it is found liable to certain imperfections, not essentially existing, but almost always involved during its preparation, and fatal to its use. These are so important and difficult to be avoided, that Science is frequently stopped in her progress by them; a fact fully proved by the circumstance, that Mr. Dollond, one of our first opticians, has not been able to obtain a disc of flint glass of English manufacture, of four and a half inches in diameter, fit for a telescope, within the last five years, or a similar disc of five inches in diameter within the last ten years.

The properties of transparency, hardness, and a certain degree of refractive power, may be easily obtained, but there is one condition essential in all delicate cases of application, which is not so readily fulfilled, that is to say, perfectly homogeneous composition and structure. Although every part of the glass may be as good as possible, yet without this condition they do not act in uniformity with each other; the rays of Light are deflected from the course they ought to pursue, and the piece of glass becomes useless. The streaks, striæ, veins, or tails which are seen within glass, otherwise perfectly good, result from a want of this quality; they are visible only, because they bend the rays of Light which pass through them from their rectilinear course,

and are constructed of a glass having a greater or smaller refractive power than the neighbouring parts. Mechanical
Processes.

These difficulties, as has been before observed, have induced several men eminent in Science to labour earnestly for years together, in hopes of surmounting them. Among these, Guinand has been one of the most successful, having produced discs perfectly homogeneous, of larger diameter than had previously been done. This persevering and ingenious man was the son of a joiner, residing in a remote village among the mountains of Neufchatel in Switzerland, and was himself brought up as a cabinet-maker. He became afterwards a clock-maker, which business was sufficiently lucrative to afford him the means of indulging his scientific and mechanical taste. He was led to the science of Optics, by accidentally seeing an English refracting telescope; and afterwards hearing of the difficulty of obtaining good flint glass, and that a prize had been offered for the discovery of a perfect process, he commenced a set of experiments on the subject, which has been attended with results highly beneficial to the Science of Optics, and which, considering the limited means possessed, entitle him to a high rank as a man of Science.

The ingredients and compositions which he employed appear to have been kept a secret, but the following facts relating to some of his operations, which appeared in the 38th Number of the *Quarterly Journal of Science*, are highly deserving of insertion in this place.

After considerable difficulties in obtaining proper furnaces and crucibles, he at length obtained a block of glass of about two hundred weight, which after having sawed in a vertical direction, he polished on one of the sections, in order to examine what had taken place during fusion, and the following were the appearances:

On the upper surface of the vitreous matter, there were many little semi-globules, which had the appearance of drops of water, terminating by a thread or little tube of greater or less depth, at the extremity of which there was a small spherical bulb. This appearance was owing to these drops and tubes consisting of a denser kind of glass than the rest of the block. In another part there arose from the bottom of the crucible other cylinders or tubes, terminating also in a kind of swelling or bulb, which had a hollow appearance from being formed of a substance less dense than the rest of the glass; and lastly here and there were seen specks ending with a tail or train of a substance also less dense than the rest of the mass in which they floated; these, on account of their appearance, Guinand denominated comets.

The following is M. Guinand's explanation of these effects. Having often seen on the surface of his glass small globules of lead, he supposed that, from some cause or other, particles of the lead which composed his vitreous matter separate from it, and appear on the surface in their metallic state; which becoming again oxidized by contact with the air, or re-calcined after being resuscitated, (to use his own expressions,) they combine with the vitreous matter on which they rest, and thus cause, in the place where they occur, that glass to be of greater density which appears on the surface in the form of drops. The specific gravity of this substance draws it to the bottom of the crucible; but in descending more or less slowly according to the temperature of the furnace, it leaves in its passage a train which occasions those threads of glass possessing a stronger refraction. Having reached the bottom, this vitreous matter, in some degree saturated with minium, being a powerful

Guinand's
theory of
the cause of
the imper-
fections in
glass.

Manufactures.

substance, attacks the material of the crucible, and forms with it a vitreous compound, of an inferior density to the mass, which ascending in consequence of its specific levity, produces those cylinders or tubes formed of a less refractive glass. Lastly, when this solvent, by melting the surface of the crucibles, especially that of the bottom, has detached from it a grain of sand or baked clay, this half-molten grain rises and floats in the mass in an oblique direction, because being still attached to a part of the vitreous matter which it has produced, it is not actuated on all its points to ascend with equal rapidity.

Whatever may be thought of this explanation, the original cause of the non-homogeneity of strongly refractive glass being once ascertained, the question of the means of remedying it still remained to be solved; and it was here in particular that M. Guinand had great obstacles to surmount; so that the sacrifices and exertions which he had previously made were trifling, compared with those which he afterwards underwent for the purpose of removing these various defects, and of rendering his glass homogeneous.

After many expensive trials, M. Guinand was so fortunate as to obtain a glass, of which some parts were perfectly homogeneous, and therefore destitute of those striæ or threads from which flint glass is so rarely found free. He reflected on the different circumstances which in this experiment might have contributed to so happy a result, so that in subsequent attempts he obtained blocks of glass possessing larger portions of homogeneous substance, and at length is said to have arrived at a certainty of obtaining, in the fusion of from two to four hundred weight of glass, at least one half of that substance perfectly free from defect.

When M. Guinand first obtained blocks containing portions of good glass, his practice was to separate them; by sawing the blocks into sections that were horizontal or perpendicular to their axis, then polishing the sections, he selected the portions adapted to his purpose, and returned the others to the crucible; but independently of the tediousness of the labour, and the waste occasioned by sawing, this process was attended with the great disadvantage of not cutting the finest parts of the glass in the manner best calculated to obtain discs as large as possible, for frequently the most homogeneous parts were thus divided; but a fortunate accident, of which he availed himself with his usual adroitness, conducted him to a process more simple and better suited to the attainment of his object.

One day, while his men were carrying a block of this glass on a hand barrow to a small water saw-mill which he had established at the fall of the Doubs, at the distance of half a league from his abode, the mass slipped from the bearers, and rolling to the bottom of a steep and rocky declivity, was broken into several pieces; M. Guinand was at first grieved at this mishap, but having selected those fragments which appeared to be perfectly free from defect, he succeeded in softening them in circular moulds in such a manner, that on cooling he obtained discs that were afterwards fit for working. Henceforward he adhered to this method; and he also contrived a mode of cleaving his glass while cooling, so that the fractures would follow the most faulty parts.

When flaws occurred in large pieces of glass, he removed them by cleaving the pieces with wedges, and melted them again in moulds which gave them the form of discs, generally taking sufficient to allow a little of the glass to project beyond one of the points of the edge,

so that the opticians who work them might be enabled to use that portion of glass in making a prism, which should give them the best measure of the refractive power, and thus obviate the necessity of cutting the lens. The refraction of M. Guinand's glass varies almost at every casting, while, on the other hand, each of the castings is of such homogeneity, that the refractive force of two pieces taken indifferently, one from the top and the other from the bottom of the crucible, is absolutely the same. This mode of fabricating glass from pieces rough and shapeless in the first instance, and afterwards remolten into discs, renders the process of M. Guinand absolutely different from that of other glass-founders, who proceed either by casting or blowing.

When the discs obtained by this process are still defective, as sometimes happens, and especially with those of large dimensions, M. Guinand obviates the defects by means of the wheel; (*roulette*;) then by softening them again, the vitreous matter expands and fills up the hollows which have been made; if, after polishing, he finds them still defective, he repeats the process until the discs are as perfect as he could wish. By these means he has often succeeded in soldering pieces of glass, which have left no trace of their separation. At first these pieces were only cemented, and there was frequently even air or sand between the united surfaces; in these cases he cut along the line of junction a small semicylindrical groove, in order that the vitreous matter while melting might fill it, not by flowing from its edges to the bottom, but by raising the bottom itself; and by repeating this operation a sufficient number of times, he declares that he has succeeded in effacing all traces of junction.

(700.) We have now to speak of the experiments of Dr. Faraday, whose labours in the promotion of this object, so important to Science in this instance as well as in many others, will always call forth the gratitude of his countrymen.

The proportions of ingredients made use of by Dr. Faraday, in the composition of his glass, have already been described in Article 679; it is only therefore necessary at present to speak of the apparatus and processes employed by him, upon which so materially depend the success of the operation.

He employed two furnaces, the first of which was termed the *rough glass furnace*, and consisted of an iron box 30 inches long, 14 wide, and $8\frac{1}{2}$ deep, which formed the interior. It was entirely open at the top, and in part at the bottom, where a fire grate was placed; it was provided with a common iron furnace door in front, and at the back with a funnel pipe to connect it with a powerful flue. The sides of the box and such parts of the bottom as were not appropriated to the fire grate were lined with fire-stone. The grate was 12 inches long by 8 wide, and the part above was closed by a fire tube two inches thick and 12 square, which resting on the edges of the lining formed the part intended for the coal fire, leaving it $5\frac{1}{2}$ inches in depth from the covering tube to the grate. The other part was covered by an iron plate, which, resting upon the edges of the lining, inclosed a space for the reception of the crucibles which was provided with holes for the purpose. The crucibles were of porcelain biscuit, perfectly pure and white, 5 inches high outside, $3\frac{1}{2}$ inches diameter at top, and $3\frac{1}{4}$ at bottom, and as thin as possible, of the finest and most refractory kind of ware, baked at a high temperature. The covers to the crucibles were evaporating basins about $4\frac{1}{2}$ inches in diameter, which were slung

Mechanical Processes.

Experiments of Dr. Faraday.

Furnace.

Manufac-
tures.

with their edges downwards by a piece of platina wire, which, being bent in the middle at an angle and stretched across the outside of the basin, had its ends formed so as to engage the opposite edges. The extremity of an iron rod, passed under the loop thus formed, served to remove the cover from place to place.

Process of
manufac-
ture.

The heat was not altogether given by flame; but, while coal was used in the fire place, coke was applied between the crucibles, and arranged throughout the unoccupied holes. A portion of the rough materials properly cleaned and prepared were introduced into the crucible, and a low heat kept in the furnace, so that they were by degrees converted into glass. Before the first charge was entirely melted, a second was put in, and sometimes a third, according to the quantity of glass present, and the soundness of the crucible. When all is fused, the temperature is allowed to rise, but not too much, lest action upon the crucible to a serious extent might occur; the glass is then well agitated and mixed by a platina rake or stirrer. Finally, the glass is either transferred by a platina ladle into trays roughly turned up out of old platina foil, or into a clean, deep, white earthenware vessel, containing much distilled water. In the latter case it was obtained in a divided state, and when drained was dried on the sand bath and put up in clean bottles.

The rough glass, thus prepared, is in the next operation to be converted into an annealed and finished plate, which is effected by casting it in a platina vessel of the required dimensions, formed out of a platina plate by turning up the sides. Dr. Faraday states, that it is of importance that it should be formed out of the best platina, rolled very carefully, so that no holes occur, and of such thickness that one inch should weigh as much as 17.5 grains.

Finishing
furnace.

The platina vessel is placed in the second furnace, termed the *finishing furnace*, which is constructed principally of brick work, and in the shape of a parallelopiped, containing a fire chamber 25 inches long, and 12 $\frac{1}{4}$ broad. The fire place is at one end, and the course of the flame and smoke is directed from that to the other by a flue which passes under the chamber. A trough made of rolled iron occupies the lower part of the ash pit, which, being preserved full of water, is sustained at a boiling temperature by the radiation of the heat and hot ashes which fall into it, and causes the passage of steam beneath the bars, which Mr. Faraday states to have found of considerable utility in keeping the bars clear of clinkers, which would otherwise impede the free passage of the air.

In addition to the fire place, the furnace is provided with an opening beneath the chamber, in which coke is used, and which acts both as a furnace and a flue.

The platina trough being carefully adjusted in its position in the chamber by pieces of tile, &c., and filled with a proper quantity of rough glass, and covered over, a fire was lighted in the furnace, and properly attended to, that the temperature might be properly sustained. The glass may with propriety be examined once early in the experiment, for the purpose of ascertaining that the tray and its contents are safe; but it is usually left for six, or eight, or a greater number of hours, that the whole may fuse, the temperature rise, and the bubbles escape.

There are two conditions of the finished glass, each of great importance, which it is the object of the process to obtain in this state of the substance. One, the most

essential, is the absence of all striæ or irregularities of composition; the other the absence of even the most minute bubbles. The first is attained by agitation and perfect mixture of the whole; the latter principally by a state of repose, so that the means required to be successful on each point are directly opposed to each. Were the glass incapable of change, by the long-continued action of heat, it would be easy to render it uniform by stirring, and then to leave it in a quiescent state, until the bubbles had disappeared; but from the length of time which it required to liberate bubbles even from small pieces of glass, without stirring, Dr. Faraday was induced to conclude that the evolution of gaseous or vaporous matter had not ceased upon the first fusion of the materials, but that the glass itself when highly heated continued to evolve small portions for some time. It occurred to him that its formation might be hastened and final separation advanced by mixing some extraneous and insoluble substance with the glass, which should act as a nucleus.

The substance which he resorted to for this purpose was spongy platina, this being a body solid at high temperatures, uninfluenced by the glass, easily reduced to powder, and likely to retain its finely divided condition during the operation, and he found it to assist powerfully in the evolution and separation of the bubbles, and afterwards to sink so completely to the bottom, that not a particle remained suspended in the mass.

The best time of introducing the platina, and the times of stirring, were points upon which Dr. Faraday was not fully satisfied, but, in the greater number of the experiments, it was sprinkled over the surface of the well fused and highly heated glass at the period of the first stirring. This method had the advantage of bringing the assistant substance into contact with the glass, when the latter was highly disposed to throw off its gaseous matter, and to allow of thorough mixture; but it also causes the addition of fresh glass, after the concoction of the materials has been proceeding several hours, in consequence of the platina being prepared by diffusing it with pulverized glass.

On other occasions, the prepared mixture of platina and glass has been introduced into the tray at the period when it was charged with the due quantity of rough glass, and before the application of fire. Particular attention was then paid to its general diffusion throughout the mass, and on these occasions its action commenced the moment the glass in contact with it was fluid. Faraday states, that he is inclined to believe that the latter will ultimately prove to be the better method, both from the greater length of time the platina acts, and for the facility and convenience of its introduction.

We must not conclude this section of the article, without adding to the names of those who have laboured at the solution of the same practical problem that of the late lamented Fraunhofer, the chief of the celebrated establishment of Berne, whose experiments were attended with considerable success; but we regret to say that the ingredients and processes which he employed are not known, and the Art has probably died with him.

Articles manufactured by the Blow-pipe.

(701.) Thermometer and barometer tubes, and a variety of ingenious toys, and other small articles of glass, are made by a lamp and blow-pipe. The usual apparatus

hofer.

Manufactures.

of the glass-blower is very simple, consisting of a sol table, at the bottom of which is placed a double bellows with a foot-board, that the artist may work with his foot and keep both hands at liberty. A pipe proceeds from the bellows to conduct the blast to the lamp, which consists of a large bundle of cotton threads lying in a tin vessel of a horse-shoe shape, and fed with lumps of tallow heaped up beside it, which, being from time to time drawn forward into the flame, keep up the combustion. The blast-pipe is brought in such a direction as to drive the flame in a contrary direction to that in which the artist sits, so that he is not in any degree incommoded by it. The remainder of the apparatus of the glass-blower consists of a few simple iron tools, such as small forceps, files, &c., and an assortment of glass tubes of different bores and thicknesses, made at the glass-house by pulling out rather suddenly a bottle of blown glass while quite soft.

The flame when in full vigour is a jet of about four inches long, of a blunt spear-head shape, which, at the extremity, is of a pale yellow, and, nearer the wick, of a blue colour. The tubes are heated gradually by being held first in the yellow and then in the blue, which is the hottest part of the flame: the blast is then put on, which very soon brings the glass to the state of fusion. The flame is strong enough to bring to a very white-red heat a solid mass of glass about as big as a child's marble, or even larger, which, when blown out very thin, will make a bulb of the capacity of full three ounces, which is nearly the extent of the power of the common lamp blowing.

Thermometer tubes.

To form each thermometer tube, they are first sealed hermetically at one end, by simply holding one in the flame a little time, and then slowly turning round, which will cause the end to melt, and, by falling in, to close the cavity. As an additional quantity of glass is required to form the bulb, an iron instrument is pressed upon the end while hot, which will consolidate it and shorten it a little. The open end of the tube must then be placed to the lips without loss of time, and by blowing steadily the lump of glass will immediately open into a bulb, the size of which will depend upon the continuance and strength of the breath.

In sealing a tube hermetically, when a bulb is not required, it is necessary to reduce the quantity of glass at the end, or the button (the term given to the end of the tube) will be too clumsy, and, from its thickness, be in danger of breaking from cooling. This is done by applying a piece of another tube of nearly the same size, to stick firmly to it, and then, by heating it for some distance at the end, and drawing the tubes in contrary directions from each other, the thickness of the tube, as it approaches the end, will be so diminished that, when sealed, an equal thickness will be preserved throughout.

Barometer tubes.

Barometer tubes require to be bored, which is done, in tubes of narrow bore, by simply holding them in the weaker part of the flame, so as to soften about an inch or two of the length, and then bending them slowly by the hand into the required shape. But if the tube be wide and the glass thin, this way of bending entirely destroys the cylindrical form of the bore, at the bent part making a double flattening. To avoid this, the tube is first sealed up at one end, and, while bending, a person blows steadily into the open end, and with sufficient strength to counteract the falling in of the sides of the bending portion, and keep the bore cylindrical. The closed end is

then cut off, by making a deep scratch with a three-cornered file, and then breaking the tube by a smart pull in such a direction that the scratched part will be outermost, which will separate it, in general with great accuracy, at the required point.

Mechanical Processes.

Glass, when in a fused state, is so tenacious, that it may be spun out, by means of the blow-pipe, into threads of such fineness, they may be wound almost like common thread without breaking; in fact, this material is so perfectly ductile, that the expert glass-blower may form, not only a great variety of interesting and beautiful toys, but little implements useful in Chemistry, and even for domestic purposes.

Manufacture of Flat Glass.

(702.) This material, although not so brilliant as flint glass, is much more perfect, and can be obtained in much larger masses, free from striæ, or other irregularities of composition. All mirrors, looking-glasses, &c., are made of this glass, and many other articles too large to be manufactured in flint glass. It is also useful for optical purposes, being employed with the flint glass to form object glasses.

Plate glass manufacture.

The greater number of plates of glass are executed by blowing, but as this operation is performed in the hand, plates exceeding a certain weight cannot be manufactured in this manner, and, in consequence, for those of larger dimensions, the operation of casting is had recourse to. The process for making blown plate is as follows.

When the contents of the crucibles are thoroughly refined, and brought to the proper state for working, a workman goes into the ash-pit, and very carefully closes up the openings between the bars of the grate with a composition, consisting of clay and cut straw, to prevent the introduction of any air into the furnace through the fire-place, which would endanger the rupture of the pots, and produce too rapid a cooling of the furnace. The metal is thus allowed to cool gradually down to the working state, which generally takes nine or ten hours after the orifice has been closed. It is now modelled in a manner similar to that used in flint glass, already described. A workman dips an iron pipe into the crucible, and having taken out a little of the fused glass upon the point of the iron, waits a moment till it has adhered; he then dips it again, and rolls another portion round the former, which he repeats until he finds he has taken up enough for his purpose. He then, by blowing down, produces a globe which, by repeated heating and blowing, he enlarges to a diameter of 12 or 14 inches, or more, according to the size of the intended glass plate.

Manufacture of blown plates.

It is now necessary to convert this globe into a cylinder, which the workman effects by giving to the rod to which the soft glass is attached the motion of a pendulum. It is then heated afresh at the mouth of the furnace; a hole is punched with an iron chisel and mallet in the centre of that end of the cylinder which is furthest off the working rod. The orifice which has been thus made is afterwards widened by an instrument kept for the purpose; and then, a pair of shears being introduced, a slit is made in the cylinder of glass, extending to one-half its length. It being necessary, however, that the cylindrical form should for the present be preserved, another workman applies a temporary rib of glass, which has been previously attached to a working rod, across that end of the cylinder which has

Manufac-
tures.

thus been cut open; and when this is done the other rod is detached, in order to allow of that end of the cylinder being also heated, opened, and slit up with shears. The whole of the cylinder being thus divided, the pontel is detached from it, and the glass is carried to the spreading oven, where it is laid upon an elevated floor covered with a thick stratum of sand, to prevent adhesion of the glass in its softened state. In a few minutes it is pushed to an adjoining apartment, where it is quickly placed in a vertical position to anneal. The annealing kiln or oven having been thus filled with the plates of glass, each standing on its edge, the doors and chimney are closed and carefully luted with clay, to prevent the possibility of any cold air entering the chamber for the space of twelve or fourteen days; after which the lutings are gradually loosened, and the glass is removed to an open part of the glass-house, to attain, by degrees, the temperature of the surrounding atmosphere. When an hour or two has elapsed, these plates may be carried with safety to the cutting room, where they are turned round the edges with a diamond, or by other means, to prepare them for the operation of grinding.

Grinding.

(703.) For the operation of grinding, the plates of glass are bedded in a horizontal position in plaster of Paris upon a table or frame made either of freestone or wood. Another plate being then reversed and suspended over the first, the material employed in grinding their surfaces is introduced between the two, and they are made to rub steadily and evenly upon each other by means of Machinery put in motion by the steam engine. When one side of the plate is done, the plaster which cemented it is picked off, the plate turned, and the opposite side ground in the same manner. The process lasts about three days, and, towards the end, the pressure is increased by loading the upper plates with flat stones of different thicknesses. It was formerly usual to employ river sand as the grinding material, a circumstance which entailed considerable loss and waste upon the manufacturer: the glass which was ground off, and which usually amounts to one-half the weight of the plates as they are cast, being thus mixed with this material, was rendered unfit for any purpose of glass-making, except that of making black bottles. Mr. Parkes calculated that the loss of real glass at the London plate house could not be less than two tons per week. This led to a patent being taken out by Mr. Heard, late chemical manager at the works at East Smithfield, for a means of saving the whole of this refuse, which consisted in grinding the plates with pure flint instead of river sand. Three or four tons of the prepared flint employed by Mr. Heard are equal in effect to twenty tons of sand; the work is done in much less time, and the abraded matter, instead of being a cumbrous and useless mass, is admirably adapted to the purposes of the manufactory, and capable of yielding a considerable profit.

Smoothing.

When the glass is by this means reduced to a plane surface, the next process is that of smoothing, which may indeed be considered a continuation of that of grinding, the object being that of reducing the inequalities of the surface, and preparing it for the last operation of polishing.

Preparation
of the
emery

Emery is the substance employed in smoothing; it is prepared by putting a considerable quantity into a vessel containing water, and stirring it about until the whole is mechanically mixed with the water. The emery being insoluble in water, if the mixture is allowed to rest for a sufficient time, the whole subsides in layers, the coarsest and heaviest particles sinking first,

and so on successively, until the very finest particles range themselves as the upper stratum. Previously to this, however, and while these fine grains are still suspended in the water, it is poured into a separate vessel, and the emery there allowed to settle. A fresh supply of water is poured into the first vessel, the contents of which are again violently agitated, and allowed partially to subside as before, but for a shorter time, so that emery of a second degree of fineness is separated. This operation is repeated, in order to obtain powder having four different degrees of fineness; the deposits are then separately dried upon a stove to a proper consistence for making them up into small balls, in which state they are delivered to the workmen. In smoothing the glass, the coarsest emery is of course used first, substituting that of a greater degree of fineness as the work proceeds.

Mechanical
Processes.

(704.) The completing process is that of polishing, which is performed by a substance termed *crocus*, a brown-red oxide of iron, found remaining in the retorts after the distillation of the acid from sulphate of iron. The instrument in polishing is a piece of wood covered with several folds of woollen cloth, each fold having between it some carded wool, so that the whole forms a tolerably hard but elastic cushion, which is furnished with a handle for the convenience of the workman.

This operation is performed by hand. The plate being imbedded in plaster upon the table, in the manner already described, and the polishing instrument wetted by means of a brush, and covered with *crocus*, the workman performs the operation by rubbing the cushion backwards and forwards over the surface of the plate, commencing at the corner, and completing each part as he proceeds. Considerable practical skill and dexterity are required to give a uniform degree of polish all over the plate, and the finishing touches require to be given with care and judgment.

The plate is turned after one side is polished, the previously polished side being provided with a coating of red *crocus*, as the white plaster would otherwise hinder the workman from forming an accurate judgment of his progress in this second operation. When the workman is satisfied with the result of his labour on this second surface, the plate is taken from the table, and, being cleaned, is laid, each side in its turn, upon a dark-blue or black cloth, which, as it admits only a moderate light, exhibits any parts which may be less elaborately polished; these must be retouched by a small cushion. When the polishing has been satisfactorily completed, the plates are washed with water and removed to the warehouse for sale.

(705.) *Cast plates.*—The manufactory at Ravenhead, which, we believe, is the only important one for cast plates in this Country, has, ever since its first establishment in the year 1771, been carried on with such a degree of secrecy that little is known of the processes and operations employed in making the best plate glass. Mr. Parkes, in his Work entitled *Chemical Essays*, gives much useful information, which he states himself to have received by various channels, and we avail ourselves of the same for the following account of these works. When the glass is thoroughly refined, it is filled into a vessel termed the cistern, which is previously heated to a temperature equal to that of the glass. A copper ladle, ten or twelve inches in diameter, fixed to an iron handle, is plunged into the glass pot and brought up filled with melted glass, which is transferred to the cistern; the ladle during this transference is sup-

Manufac-
tory at
Ravenhead.

Manufac-
tures.

ported on a strong iron rest placed under its bottom and held by two other workmen, which is necessary to prevent the bending and giving way of the red hot copper under the weight of fluid glass which it contains. When, by successive lading, the cistern is filled, it is suffered to remain for some hours in the furnace, that the air-bubbles occasioned by this disturbance may have time to rise and disperse.

It is then removed to the casting table, which consists of a cast-iron plate fifteen feet long, nine wide, and six inches thick, supported upon strong pillars, and furnished with ribs of iron at the sides and end, which are moveable and can be adjusted nearer together or further asunder according to the size of the plate intended to be cast. These were originally made of copper, but in consequence of this metal being found liable to crack from the sudden access of heat that accompanies the pouring over of such a torrent of melted glass, the British Plate Glass Company determined to make a trial of iron, and had a table made of the dimensions above described, which has fully answered the intended purpose, having, during several years of constant use, stood uninjured throughout all the violent and sudden alterations of temperature to which it is exposed. The table is so massive, weighing nearly fourteen tons, that it became necessary to construct a carriage purposely for its conveyance from the iron foundry to the glasshouse. It is supported on casters for the convenience of readily moving it towards the mouth of the different annealing ovens.

The foundry in Ravenhead, where this table is used, is said to be the largest room under one roof in this Kingdom; it is 339 feet long, 155 feet wide, and proportionally lofty. Westminster Hall, to which the superiority in this respect is commonly ascribed, is smaller; its length being 300 and its breadth only 100 feet. The melting furnaces, which are arranged down the centre, occupy about one-third of the whole area of the apartment, and the annealing ovens are placed in two rows, one on each side of the foundry, and occupy the greatest proportion of the side walls, each being 16 feet wide and 40 feet deep, and their floors being level with the surface of the casting table, the plates of glass may be deposited in them immediately after they are cast with little difficulty and without delay.

Operation
of casting.

(706.) When, from the inspection of the samples taken out, the melted glass is found to be in the exact state that experience has pointed out as being most favourable for its flowing readily and equally, the door of the furnace is opened and the cistern removed to the casting table, which is previously heated by hot ashes and wiped quite clean. Any scum which may have collected on the surface of the melted glass is then carefully removed by a copper instrument, as the mixture of any foreign substance with it would infallibly spoil the beauty of the plate. The cistern is then hoisted up by tackle or a crane, and swung so as to be over the upper end of the casting table, and then overset, which causes a thick flood of melted glass to flow and spread in every direction upon the table; the surface of the glass, while still in the semifluid state, is then made quite smooth and uniform, by passing over it a heavy copper roller, turned very true in a lathe. This roller rests upon ribs on the table, and consequently reduces the glass to a plane surface, having a thickness equal to the height of the ribs from the surface of the table, and width equal to the distance between the ribs, but the length depends upon

VOL. VII.

the quantity of metal in the cistern. Should the quantity of metal exceed that required for the full dimensions of the table, the metal rib is removed from the lower part, and the surplus glass is received in a vessel of water placed under the extreme end for the purpose; but if the glass falls short of the required quantity, the moveable rib is shifted up the table, to give a square termination to the plate, in order that no unnecessary waste should occur. This operation is said to be very interesting; the spectacle of such a large body of glass poured at once upon a metallic table of great magnitude is very grand: the variety of colours also which the plate exhibits immediately after the roller has passed over it renders this an operation very splendid and interesting.

The number of workmen required for the whole process is at least twenty, each of whom has his particular duty assigned him. From the time the cistern is removed from the furnace to the completion of the casting, by the glass becoming hardened, the apartment must be kept as free as possible from disturbance; even the opening and shutting of a door might, by setting the air in motion, disturb the surface of the glass, and thus impair the value of the plate.

As soon as the plates become fixed by cooling, they are thrust by main strength off the table, and gradually slipped into the annealing oven immediately contiguous, where they are treated like the smaller plates already described, except in the circumstance of their being spread out one by one in a horizontal position, instead of being piled on their edges as before mentioned.

When the plates have remained about twelve or fifteen days in the oven, the process of annealing is complete, and, after a strict examination by the inspector to see if each is free from flaws, nothing further remains to be done than the grinding, smoothing, and polishing, which operations are performed in the same manner as those on the smaller plates already described.

The great size to which founders are now enabled to get these plates is very astonishing. The proprietors of the above Company have announced that they have on sale plates of the enormous size of 6 feet by 12 feet each, equal to 72 feet of surface, which, to obtain perfectly true and free from flaws, may be considered the effect of great skill and ingenuity. From the liability to holes and other flaws, which render it necessary to reject numerous plates, the expense of the larger ones increases in a great ratio, as will be seen from the following list of the prices of the Company.

Crown Glass.

(707.) This is the description of material of which the greater part of glass for windows is composed, although some of the larger sort, such as those used in shop win-

Mechanica
Processes.

Manufac-
tures.

dows, are too heavy to be executed in the manner in which this material is manufactured, and are in consequence made of plate glass by casting.

The commencement of the process is the same as in blowing flint and plate glass; viz. the workman dips into the crucible of melted metal, reduced to the proper heat for working, until a sufficient quantity is collected to form a plate of the intended dimensions, which is commonly $9\frac{1}{2}$ pounds; this is effected by three successive dippings, and, by long practice, he will gather the same weight within two or three ounces. He then alternately blows down the tube, and rolls the expanded glass on a flat iron table, till it has got the figure of a flask, and is nearly of equal thickness throughout: it is then flattened at bottom, which completes the first part of the operation. An assistant now dips a solid rod into the pot, and, taking out a little glass on the end of it, applies it at the centre of the flattened bottom of the flask.

Having by means of this lump of fresh glass attached a new working iron, it becomes necessary to withdraw the former, which is effected in the usual manner, by a workman, who wets the end of a small iron utensil with a little cold water; with this he touches the glass at the point, where it produces a crack, so that by a sharp stroke the old instrument may be detached from it, which leaves a hole in the piece of glass about two inches in diameter.

A new working iron being thus attached to the glass, exactly at the opposite point to that where the former one adhered, the workman carries it by the present or new rod to the flasking furnace, and holds it for a few minutes at a small opening, termed the nose hole, turning it gently in his hand all the time. The small hole in the furnace is contrived merely for the purpose of heating that part of the glass to which the cold water had been applied. By this means it is put in a proper condition to be introduced into the larger opening of the furnace, where it is heated by degrees until the mass becomes sufficiently ductile for further working. He then begins to turn it quicker and quicker, holding it the whole time at the mouth of the oven, till it becomes so much softened, that, merely by the centrifugal force communicated by the rapid motion of the instrument to which it is attached, the whole mass opens itself by degrees, extending further and further till it suddenly assumes the shape of one immense circular sheet of glass 40 or 50 inches in diameter, and of one uniform thickness.

This operation is called *flushing*. There is exhibited in the performance of it a great degree of dexterity, and altogether, from the unexpected changes of shape which take place from the different manœuvres of the workman, it excites a greater degree of interest to the visitor than perhaps any manufacture in this Kingdom.

The sheet or table, when thus completed, is laid by a fork upon a bed of ashes, and the rod cut from it by means of a pair of shears, a knot or burr being left behind. It is then set up in the annealing arch, where it is kept for four hours at a dull red heat, and then thirty-six hours more to cool. The diameter of the sheet is 4 feet, and the working off by each pot produces about 180 sheets. For the convenience of packing, each table is divided as equally as possible, consistently with having the whole of the burr in one of the pieces. The thickness of the glass is nearly equal in every part, except in a circle extending a few inches round the burr. In cutting it up for use the burr is left in the middle of a square pane, which is employed only in glazing cellars and outhouses.

Although, as we have just stated, these lumps of glass are only used for glazing in places where strength is more an object than beauty, yet the glass in such pieces is frequently so perfect as to be worked into the crown lenses of telescopes of the smaller kind. It is singular, after the mode of manufacture above described, that any glass of this kind should be fit for optical purposes. It appears, however, that our first English opticians generally prefer it to plate glass, although the slight tinge of green which it always has necessarily intercepts a certain portion of light; the image, however, of a star formed from an object glass of flint and crown, is seen with a more defined disc than from those made of flint and plate, thus fully compensating the astronomer for any trifling loss of light he may sustain from the colour.

(708.) *Broad glass*.—It is evident that there is a natural limit to the size of the tables made, as above described, it not being possible for a man to blow a flask much larger than is required to form a table of the usual dimensions, and the size of the pane of glass that can be cut from such a table is further limited by the knot which occupies its centre. But for picture frames, and for the larger kind of window glass, plates larger than can be cut out from any table are wanted. Such plates are called broad or spread glass, or German sheet, whether made here or imported from Germany, whence they were originally derived.

The largest tables manufactured are 5 feet in diameter, and the largest square that can be cut from such plates is 36 inches by 24; but broad glass may be had 42 by 28 inches, by first blowing it into a flask, then taking off the flask by means of the solid rod, as already described, and forming it into a cylinder. It is then taken from the rod in the shape of a hollow cylinder, open at both ends, and heated in order to be separated throughout the length by a pair of shears, it is then expanded on a hot plate, and made even by pressure.

(709.) *Annealing*.—In annealing crown and broad glass considerable nicety is required in regulating the temperature of the annealing arch, as a small excess of heat would render the plates so soft that they would bend out of the perpendicular and be much injured. On the contrary, if the furnace be not hot enough, there is great danger of the plates flying in pieces; but if this should not happen, this defect would inevitably be discovered by the glazier, because glass imperfectly annealed is operated upon by the diamond with great difficulty, and it is almost impossible to cut it with exactness.

Crown glass is sold according to its quality under four different denominations; firsts, seconds, thirds, and fourths, at considerable difference of price, that of the fourth's quality yielding to the manufacturer scarcely one half of the first. These variations arise partly from the goodness of the materials, but are considered to be principally owing to the want of sufficient care in maintaining the necessary degree of heat in the furnace. If this is suffered to fall, it is difficult, owing to glass being a bad conductor of heat, to raise it to the former degree. In the operations of the glass-house it does not often happen that beyond one-third of the quantity made is of the first quality, the largest proportions of the produce being composed of seconds and thirds.

(710.) *Bottle glass*.—We have still to mention the manufacture of bottle glass, which, however, differs so little from the methods employed in forming bottles in flint glass, that little requires to be said on the subject. The glass is collected on an iron tube and blown into a globe, from

Mechanical
Processes.

Broad
glass.

Annealing.

Bottle
glass.

Manufactures.

which it is fashioned, by means of a few iron tools of different shapes, into the article required, excepting half-pint, pint, and quart bottles, which are blown in a case either of iron or brass. All these goods are likewise removed while quite hot to a furnace to undergo the usual process of annealing to render them fit for use.

Bottle glass being made without lead will bear a greater heat without melting, and is therefore more fit for utensils employed in chemical processes, where any heat is required; its chief use is, however, for common bottles, where the quality of transparency is not essential, and the consumption for this purpose is so great that the number of hands employed in the manufacture exceeds the total number employed in fabricating the remaining descriptions of glass.

On coloured Glasses.

Coloured glasses.

(711.) Although, in the uses to which glass is usually applied, the transparency and whiteness are properties much to be desired, and upon the perfect attainment of which the chief attention of the manufacturer is bestowed, yet there are many uses of this material where the colour is much desired, as in ornaments where the beauty is chiefly depending on the degree of colour. This department of the Art is carried on to a great extent, and though much of the management remains a secret, a good deal of valuable matter has been made public by the labours of Neri, Kunchel, Margraaf, Fontanieu, and other practical chemists; the following short account of which we hope will prove interesting.

The metallic oxides are the substances usually employed to produce colours on glass, and are capable, when well prepared, of giving a degree of richness and beauty of tint which is scarcely excelled by natural gems. In the manufacture of these articles the composition of glass differs from any we have previously described, and is a subject upon which a great deal of difficulty arises, as it is necessary to unite the qualities of great purity, lustre, and hardness, together with a sufficient degree of fusibility to melt at such a heat that the oxides will not be decomposed, which qualities, from the circumstance of the oxide of lead, which gives the greatest lustre, also rendering them soft, it is evidently difficult to combine in the same material.

We do not conceive it necessary to enter into a description of the various compositions employed in forming artificial gems, but refer the reader, desirous of such information, to the articles Glass in the *Encyclopædias* of Dr Brewster and Dr Lardner, and to Aikin's *Chemical Dictionary*. We content ourselves with giving the following account of the properties of the salts and oxides of some of the principal metals, for which we are indebted to the last-mentioned work.

Colouring properties of gold.

Of gold.—This metal in a state of minute division and oxidated has long been celebrated for giving glass a most exquisite purplish-red, resembling the ruby, and almost equalling it in beauty. It is both the most expensive and most splendid of all the artificial gems or coloured glasses, but in the management it seems to be very difficult to obtain complete and uniform success, which is principally owing, it is supposed, to the great tendency of gold to assume the reguline state from mere heat, by any carbonaceous vapour, or by hydrogen.

The most celebrated and common preparation of gold for giving a purple to glass and porcelain is the

purple precipitate of Cassius, or gold precipitated from its nitro-muriatic solution, together with the oxide of tin. The usual way of making it is to dilute very largely a solution of gold in aqua-regia, and adding to it drop by drop a very dilute nitro-muriate of tin. The liquor immediately becomes of a purplish-red colour, and by standing a precipitate of some varieties of shade slowly subsides. A similar precipitate also takes place with the nitro-muriate of gold, and the pale muriate of tin, and also with greater certainty by immersing a stick of tin in a dilute solution of gold. This substance is an intimate mixture of the oxides of tin and gold, but the precise state of oxygenation of the tin is not well known, nor its exact use, as it is certainly not essential to produce a purple tinge in glass; many preparations of gold produce it in which not an atom of tin enters.

Another preparation of this metal used in glass colours is the fulminating gold produced by precipitating this metal from its nitro-muriatic solution by ammonia. This preparation will explode most violently when raised to a somewhat less heat than that required to melt tin, or even by moderate friction; but if kept for some time at a much lower temperature, being previously mixed with fixed alkali, it loses its fulminating property, and may be used with safety. A more manageable preparation of gold is the precipitate from the nitro-muriate, by the carbonate of potash, which is a brown-red or yellowish powder, and is not fulminating, provided the solution of gold be made with the muriatic acid, and not muriate of ammonia; it being the presence of ammonia which gives the fulminating property. For fine carmines this carbonated oxide of gold, as well as the decomposed fulminating gold, are mixed with lunar cornea, and then with the proper quantity of a saline flux, in which nitre and borax usually enter. The colouring power of these simple oxides of gold is nearly twelve times as strong as that of the purple precipitate, which is another proof that tin does not of itself add to the body of the colour.

Of silver.—All the oxides of silver give a yellow to vitrescent substances, which appear to be very pure and beautiful, but it is not often used in coloured glasses on account of the ease with which it is destroyed by too much heat. It seems to be chiefly employed for colouring porcelain and enamel, where the eye of the artist can always be on his work, and the heat is lower and much more manageable. In the latter case, the oxide of silver is generally mixed with a small quantity of alumina. The phosphate of silver, formed by adding the nitrate of silver to the phosphate of soda, is also employed.

Of iron.—The shades of colour produced by the oxides of iron are very numerous. A small portion of iron, fully vitrified with a large body of glass, gives different shades of green and yellow, and it is to this substance that the colour of the bottle-green glass seems to be owing. A larger dose of it gives a yellow, after thorough vitrification, and a still larger gives a brownish-black, which seems to be only a yellow very much concentrated, since this latter colour is again produced by diluting the brownish-black with a greater quantity of uncoloured glass. The oxides of iron also produce a red upon enamel and porcelain, but this is supposed to be owing to its being suspended in the glass flux in a state of extreme division, for when by raising the heat a complete fusion of the oxide is produced, the colour turns to yellow. This change is ingeniously prevented by combining the oxide previously with alumina, by mixing the

Mechanical Processes.

Manufac-
tures.

sulphate of iron and alumina together in solution, and precipitating both together by carbonate of potash.

A great many different preparations of iron have been used, but there does not seem any direct reason for the preference, as they will all, when fully vitrified, produce a yellow or brown, according to the dose. Brongniart asserts that the presence of oxide of lead singularly disposes the perfect oxide of iron to lose its red or rose-colour, and it is used for that purpose in enamelling.

Iron appears to be the natural colouring matter of the sapphire, lapis lazuli, and some other blue minerals, and was employed by the Ancients to give a blue colour to glass, as was proved by the analysis of some of the ancient blue enamels; but the Art now seems to be entirely lost.

Copper.

Of copper.—All the oxides and carbonate oxides of copper produce a fine green when thoroughly vitrified with any kind of glass or flux. There does not seem to be much reason for the preference of any one particular preparation, but those commonly used are the carbonated oxide produced by adding a carbonated alkali to the sulphate of copper, and copper oxidated and calcined simply by heat and the action of the air. This metal may, however, be made to give a carmine red (or, mixed with iron, a full deep red) by adding to glass containing it a quantity of tartar when in complete fusion, and working off almost immediately; a greater continuance of heat, however, restores the green colour. The oxide of copper is often mixed with manganese and iron to produce a full-bodied black glass; when combined with three times its weight of alumina in a strong heat, it runs into an opaque red enamel.

Lead.

Of lead.—This oxide is capable of giving a yellow, but is seldom used directly as a colour, on account of requiring the enormous proportion of three-fourths of the glass to give a yellow of any intensity, and this would give a compound extremely soft, and which would act very powerfully on the crucibles.

Antimony.

Of antimony.—The perfect oxide of this metal gives a full yellow to glass, both alone and in compound colours, where yellow is a necessary ingredient.

Manga-
nese.

Of manganese.—The proper colour given by this oxide is, when not in contact with carbonaceous matter, purplish-red, rather muddy when in a full body, but still very beautiful. The colour is totally destroyed by all the arsenical salts, as we have before described, and therefore arsenic in any form should be avoided when manganese is used as a colouring matter. This oxide is the principal ingredient in most of the black glasses.

Cobalt.

Of cobalt.—The colour given by the oxide of this metal is a fine blue, which is unalterable in any fire, and succeeds with any flux. Cobalt is also used for some of the finer blacks, mixed with manganese and iron, and with yellow of antimony and lead it composes a green.

Chrome

Of chrome.—This metal, which is the natural colouring matter of the ruby and emerald, would be a most valuable one if it could be procured in any quantity. It has been found to give a fine red, and also a most beautiful green to glass, but its great scarcity has prevented its frequent use.

The oxides of tungsten, nickel, and some other metals, are capable of giving colours to glass, but as their application is limited, and use consequently unfrequent, we have omitted to speak of them here. In consequence of having already exceeded the extent assigned for the present article, we must also omit any description of the valuable receipts and processes given by Kunchel, Fon-

tanieu, and other practical chemists, for the formation of particular colours, and content ourselves with referring the reader to the excellent treatise on glass in Aikin's *Chemical Essays*.

Mechanical
Processes.

Enamelling

(712.) The art of enamelling consists in the application of a thin coating of vitrified matter upon a polished metallic plate. The vitrified substances employed are of three kinds, transparent, semitransparent, and opaque, but the latter are the more commonly employed, and those which the term enamel is generally considered to signify. It is of itself a delicate white, but is susceptible of the most beautiful tints by the mixture of various metallic oxides in the composition; its natural whiteness and beautiful texture also render it particularly calculated as a ground for painting, and a degree of delicacy and richness of colour can be given on this substance not to be excelled by any other means.

Enamel-
ling.

The Art of enamelling is of great antiquity, having been practised by the Egyptians, to compose ornaments for the envelopes of their mummies. We have also various antiquities which prove that it was known to the Greeks, Romans, Saxons, and other ancient nations, but it appears to have been made use of by them only for ornamental purposes. Since the invention of watches and clocks, this manufacture has, however, become of greater importance, from being so well calculated, from its permanency and beautiful whiteness, as a material for the faces.

Antiquity
of the Art.

The composition of white enamels does not differ much from that of common glass, except in the addition of oxide of tin; the exact proportion of the ingredients is, however, a matter of some importance, in the first place to render it of a clear fine white, so nearly opaque as to be translucent only at the edges: and secondly, sufficiently fusible to run into a kind of paste which will extend freely and uniformly over the surface of the metal without fully melting into a thin glass.

Composition of enamels.—The following are the directions given by Clouet for composition of white enamel. Mix 100 parts of pure lead with from 20 to 25 of the best tin, and bring them to a low red heat in an open vessel, which causes them to burn very rapidly and oxidate on the surface; the crusts of oxide must be rubbed off as they are formed, until the whole is thoroughly calcined. A quantity of sand must be calcined with a fourth of its weight of salt, and 100 parts of the resulting substance mixed with 100 of the above oxide, and 25 or 30 of common salt, will form a composition which, by the application of a proper degree of heat, will form a good enamel. If more fusibility is wanted, the dose of oxide is increased, and that of the sand diminished, the quantity of common salt remaining the same. The sand required for this process, Clouet states, should not be of the common sort, but a micaceous sand, in which the mica forms about one-fourth of the mixture.

Composi-
tion of
enamels.

Neri, in his valuable Treatise on glass making, has given proportions of the ingredients, which vary considerably from the above, but which have been confirmed by Kunchel and other practical chemists. His directions are as follow: Calcine 30 parts of lead with 33 of tin, and take of this calcined mixed oxide 50 pounds, an equal quantity of powdered flints, (prepared by being thrown into cold water when red hot and ground

Manufac-
tures.

to powder,) and 8 ounces of salt of tartar, and melt the whole in a strong fire kept up for 10 hours. This composition produces a material of a grey-white, which is that most commonly employed for opaque enamels. To render it quite white, 48 grains of manganese must be added for every 6 pounds, and the mixture melted in a clear fire, then cooled by throwing cold water upon it, remelted, again cooled by water, and so on for several times, which will render the enamel perfectly white and fine.

Metals used
as enamel
grounds.

Metals used as grounds for enamelling.—Enamels, as before stated, are usually laid upon a metal ground, although in some cases it is used in substance, to form ornamental vessels, figures, vases, &c., by running it into moulds immediately from the pots in which it is melted; this kind of enamelling is, however, now very rarely practised. The only metals suited to the purposes of the enamels are gold and copper, all other metals being either too fusible to endure the action of the fire, not having sufficient affinity for enamel to cause it to adhere and remain attached, or exert some chemical action on it, which destroys its whiteness and beauty. Gold is unquestionably the best substance to enamel on, and it is almost always used for transparent enamels from the richness of tinge which it produces, but in the more extensive application of this art, *i.e.*, in clock and watch making, fine copper is always employed. The use of silver has been attempted, and although it has the requisite property of being unalterable by the heat necessary to be employed, yet it is found to act so powerfully on the oxides contained in the melted glass, as thereby materially to impair the colour of the article, so that its use is found in most cases inadmissible.

Enamelling Watch Dial Plates.

Watch dial
plates.

(713.) The enamels used in this extensive branch of the Art are of two kinds, *viz.*, the glass enamel, the composition of which has been described above, and the hard, or Venetian enamel, which is the most beautiful substance; but the greater care required in the manufacture renders the plates considerably more expensive, and it is for that reason not so frequently adopted as the former.

Pl. I.

Fig. 3, 4, 5,
&c.

The copper employed in this manufacture is received in thin sheets prepared for the purpose, and, after being heated, is formed by means of a die to the required convexity, and cut so that the edges extend a little beyond those of the die; these edges are afterwards rubbed down by means of a blunt tool, and by that means form a rim round the plate. An opening is made at the centre, and at any part where a second or other hand may be required, by piercing a hole from the inside or concave side of the plate, which causes a slight rim or edge to stand up above the upper surface. The tool by which this is done is shown at fig. 6. of plate I. These edges are afterwards reduced by a fine file so as to be raised the exact thickness of the intended coat of enamel. The plate, after being cleaned by immersion in water, acidulated with sulphuric acid or aquafortis, and rubbing the surface over with a scratch brush, is prepared to receive the first coating of enamel.

Preparation
of the
enamel.

The enamel is received in the shape of lumps, which are first broken down with a hammer, and then ground to a powder in an agate mortar to a degree of fineness equal to that of fine sand. It is then washed in very clear water, and, when the heavier parts have subsided,

Mechanical
Processes.

the remaining milky-looking fluid is poured off and left to settle in a separate vessel. This operation is several times repeated, so that the powder may be divided in separate portions, having different degrees of fineness.

It is necessary that both sides of the copper have a coating of enamel, to prevent the plate being drawn out of its true shape by the unequal shrinking of this substance and of the metal. For this kind of work, the counter enamel is only about half the thickness on the concave as on the convex side, but for flat plates the thickness is required to be the same on both sides. The enamel is first spread on the concave side of the plate by means of a spatula, and the plate is then laid between the folds of a cloth or napkin, in order to absorb a portion of the water, and again rendered perfectly smooth and even by the spatula. The plate being now inverted and fixed firmly in a horizontal position, a quantity of enamel is spread on the upper surface, level with the rims at the circumference and centre, and a cloth applied so as to absorb the superfluous water. The plate is then carefully examined, and the enamel rendered perfectly smooth and even by means of the spatula.

(714.) *Firing.*—It is now prepared for the operation of firing, which is performed in furnaces termed the *muffle furnaces*, of which a representation is given in plate I. fig. 3. 4. B B are two pieces of brickwork, on which rest the arch C, which covers the ash or coal pit; from each side of these piers project three bricks, E, fig. 3, which support the hearth or iron plate F; another plate of cast iron lies beneath this, which serves for the bottom of the furnace, but which is not seen in the section, and G H H are the interior sides of the furnace, which are supported upon this plate, and contained in brickwork which extends on each side over the piers. The brickwork is bound together by the iron bar I, which also serves as a support to the brickwork over the furnace.

When the fire is made up for use, the muffle is placed in the furnace, with one end resting on the iron support, as shown at L, and the other kept level with the front by putting a piece of coke under each side. The muffle is shown separately at fig. 9. The space on each side is then to be filled with small pieces of coke, and at the upper part and back of the muffle small coke must likewise be placed until it reaches about halfway up the end. A solid piece of coke must then be selected large enough to cover the end of the muffle, and upon this a second piece is placed as a supply when the first is burnt away. The fire is now lighted by introducing red hot charcoal in the space left under the muffle, and by drawing out the damper the fuel will soon be lighted all over, and the heat rapidly raised.

The method of arranging the dial plate in the muffle is represented in fig. 11, where A is the dial, which is supported upon a ring, B B, composed of pipe-maker's clay, and the two rest upon a circular flat piece of firestone or Stourbridge clay, C C, about the eighth of an inch thick. The part marked D is termed the *turner*, which is made of a spherical figure, so that the whole apparatus may be turned round upon it in any position by a pair of tongs for the purpose, shown at fig. 10, to cause the enamel to be equally well fused in every part of the plate. The planch is placed in the furnace, and, when it is heated to a white heat, withdrawn, and the dial plate and ring being arranged as shown in the figure, the whole is placed upon the turner under the muffle, and kept in constant motion by a pair of tongs,

Manufactures.

until it assumes a uniform surface, when it is withdrawn and allowed gradually to cool.

It will be found that a considerable depression has been produced in the enamel by the act of fusion, so that the edge and eye are considerably above the surface. This deficiency it is the office of the second coat of enamel to supply. When the work is cooled, the second process is commenced by removing the scale from the edges and eyes by means of a fine-grained Lancashire file or a smooth grey stone, and, after being washed and dried, the plate is securely fixed down, and a second layer of enamel gently spread with a quill, and prepared for firing by the napkin and spatula as before, and the operation of firing repeated.

Polishing.

(714.) *Polishing.*—The plates, although perfectly bright and glossy, are uneven on the surface, which has to be rendered smooth, and the glossiness again produced, before they are complete. They are taken separately, and the fine edge worn off by a species of fine grey-stone till they are smooth and even, after which the eyes are rubbed down till the centre of each plate is even and square. The irregularities of the surface of the enamel are removed either by the rag-stone or grey-stone, with fine ground silver sand and water. This is done by an expert workman, who, by giving a circular motion to the plate, is enabled to grind it with a surprising degree of regularity, rendering it perfectly smooth, but the gloss is entirely removed. They are now well rubbed over with ground glass to remove the stains which have been left by the polishing stones, and, clean water being suffered to run upon them, they are wiped dry, and again placed upon the rings for firing. The heat of the furnace must be just sufficient to run the surface of the enamel, which will recover the glossiness destroyed by the polishing, and thus render complete the fabrication of the plate.

The coarser description of watch plates are made rather differently, and are termed *run-down plates*, and *run-down one coats*, the former of which are made by laying the enamel in sufficient quantity to form plates of the required thickness without putting on a second coat, by which great time is saved, but the same degree of regularity and neatness cannot be given as in the mode above described. The run-down one coats differ from these only in being completed by polishing.

Venetian or hard plates.

(715.) *Venetian or hard enamelling.*—In enamelling the Venetian or hard plates, the coppers and first coats are prepared in the same manner as the glass enamel, except that the layer is rather thinner. The hard enamel is ground down in steel mortars to a coarse grain, and exposed to the action of aquafortis or vitriol, in order to destroy any particles of iron which may have become mixed with, and which would infallibly destroy the beauty of the enamel. The powder is then carefully washed to remove the acid, and reduced to the necessary degree of fineness in an agate mortar, and spread over the copper with a quill in small quantities, and as evenly as possible; it is then alternately dried and smoothed by cloth and a spatula as before, and fired twice. The polishing of this enamel is done first by a very fine-grained Lancashire file or smooth piece of steel and silver sand; secondly, by fine blue-stone and sand; and thirdly, the blue-stone alone. With the latter, as great a degree as possible of polish should be given to the enamel, as the plate will then be finished in the third fire with a less degree of heat than would be otherwise wanted. Much attention must be used to prevent scratches, which

cannot be filled up by the fire without a greater heat than the enamel will bear. When the polishing is complete, the plate is carefully cleaned, and, should there be any specks discovered, they must be picked out with a sharp diamond, and the hollows filled up with enamel, and the plate exposed to a fourth firing. If the part where the enamel has been added is found raised above the general surface, from too large a quantity having been used, it must be smoothed by the blue-stone, and the plate submitted to a fifth firing.

Mechanical Processes.

Hard enamel plates are always considerably dearer than glass ones, from the greater labour and attention bestowed upon them, and the best watches are always made up with dials of this kind.

Clock Dial Plate Enamelling

(716.) The processes employed in this branch of the manufacture resemble in a great measure those we have already described; in consequence, however, of the much greater size of the plates, great care and attention are required to prevent them from warping and altering their shape by the heat of the furnace. The manipulations by which this is effected, termed *planishing*, form a very important and difficult process, and quite distinct from any employed in the watch plate enamelling.

Clock dial plates.

In consequence of the difficulty of preserving a large plate perfectly flat, from the unequal expansion of the metal, a slight curvature is given to it by means of large brass dies or a Machine adapted for the purpose. This Machine consists simply of an anvil bedded firmly in a strong oak block, the face of which is made concave and highly polished; above which is suspended a hammer or monkey, having the face made in a corresponding degree convex, and which is also highly polished. When the plate is prepared by cleaning and annealing, and the holes for the hands pierced by means of an iron punch, it is placed on the anvil and a blow given to it by the hammer, which reduces the unevenness and renders it of the required curvature. A strong and uneven spring will still remain, which has to be removed by a repetition of the operation, but previously, in consequence of the hardness and stiffness produced by the hammer, the process of annealing must be again resorted to, and the copper must be cleaned and pickled as before. It is customary also, after the plate has passed through the planishing Machine, to place it in a die and subject it to a number of blows by a wooden mallet all over the surface, which is found to render the spring more uniform from the edge to the centre. It is then annealed and subjected to the operation of the planishing Machine a second time, and the same operations are repeated three, four, and even as many as seven times, with large plates, or when the metal is not of good and regular texture.

Planishing

Upon the perfect manner of performing the operation of planishing greatly depends the beauty of the manufactured article, any irregularity in the surface of the plate being very painful to the eye, and the endeavour to correct it is generally attended with great danger of totally destroying the plate. When the planishing is properly performed, the copper will flap or bend into the curve when turned either side uppermost. It is then in a fit state for receiving the enamel, for which it is prepared by the usual process of pickling and attentive cleaning.

The enamel for clock dials is broken down in a steel mortar, and afterwards cleansed and ground in one of

Manufactures.

agate, in the same way as for watch plates, but the large quantity required renders the operation much more laborious and tedious; particularly as the hard description of enamel can only be used with complete certainty. The powder which arises in grinding, and floats in the water, termed the *washing*, is frequently employed for the backening of the plates. It is, however, very liable to blister in the fire, and thereby to cause the plate to cockle or alter its shape, and for these reasons, in manufacturing the best description of plates, the enamel in substance is always employed, which renders the success of the work much more certain.

Manner of laying on the enamel. Fig. 7, 8.

For putting on the enamel, the plate is placed upon a cloth, and the backening spread on carefully by means of a small bone or ivory spoon, fig. 7, and, when the whole surface is covered, the water is partially dried by a cloth, and the enamel laid even and smooth by a spatula, fig. 8; which operations are repeated until the surface is sufficiently even and dry; then the copper is turned, and the first coat laid upon the face in a similar manner. The work is then put upon a planch for firing in a situation near the furnace, or in holes termed annealing holes, that the moisture may be evaporated previous to its introduction into the muffle. The planches are from one quarter to three quarters of an inch in thickness, depending on the size of the plates, and are made either of fine fire-stone, or of a composition of Stourbridge clay, pipe-clay, and the remains of old planches, which are pounded together in an iron mortar, and passed through a sieve. The face of the planch is either flat or rubbed into a similar curve to that of the coppers, and, before the work is placed upon it, a slight covering of whiting is sifted on to prevent the enamel from sticking to the planch when in the act of fusion.

When the muffle is sufficiently hot, the planch and copper are carefully removed from the annealing hole by means of iron prongs, which are slid beneath the planch and plated in the furnace, and when the firing is complete, which may readily be determined by the appearance of the surface of the plate, it is again removed to the annealing hole, that the cooling may be as gradual as possible. The gradual cooling is necessary to prevent the enamel cracking on the surface, which would be otherwise likely to occur from being set in the cold air, and thereby prevented from gradually adjusting itself to the contraction of the metal.

The application of the second coating is an exact repetition of the same process; we have therefore only to speak now of the polishing, in which the operation differs considerably from that employed for watch faces. The plates when cold are carefully fixed upon a bed of wet sand, so that no vacancy or hollow occurs beneath the plate, or are imbedded in a similar way with sand upon wet flannel twice or thrice doubled. When thus prepared, the surface is worn even by means of silver sand passed through a sieve, and polishing stones formed of flint pebbles, and ground to a surface. The sand is used with water, and the operation is performed by giving the polishing stone a quick circular motion over every part of the plate, till the surface is evenly reduced, which is known by the glossiness being entirely worn off; this occupies from half an hour to an hour, and sometimes more, according to the size and previous evenness of the plate. Sometimes the polishing is accelerated by using in the commencement pieces of lead and iron, but they are always finished by the polishing, which is necessary to remove the blackness or

stain produced by the metals. The plates are now made perfectly clean by fine enamel ground over the surface of each by a small mull or polishing stone, and the surface of the plate wiped with a cloth, which is employed instead of washing by water, in order that the loose enamel that may be collected in any little holes in the plates may not be removed; the plates are thus without any further trouble rendered smooth by the next operation of fusing; should any holes or specks remain after this, they must be removed and repaired in the same way as we have described for watch plates.

In preparing plates for enamel painters, after the polishing is completed, a coating of a substance termed a *flux* is laid on previous to the last firing, after which the plate is sometimes again polished, but the enamelling colours are more frequently put on in the state it leaves the furnace.

Transparent enamelling.—The operations for transparent enamels are similar to those we have already described, but as the work is generally of a more minute kind, a greater degree of delicacy is required in the operations. Watch cases are commonly enamelled upon gold as well as most of the superior articles of ornament, and the surface is frequently engraved into different figures and compartments before the enamel is laid on, by which means the work assumes a beautiful variegated appearance through the vitreous coating. In enamelling the backs and edges of watch cases, &c., quince water is frequently used as the medium by which the enamels are laid on, in consequence of its possessing a more adhesive and retentive quality than common water, and thus better prevents the enamel flowing by its gravity from its proper situation, and destroying its figure. When enamels of different colours are intended to be employed in the same article, which is frequently the case in ornamental work, small edges or prominent lines are left in the substance of the metal, which are polished with the enamel and reduced to the same equality of surface.

Gunpowder Works.

(717.) *History of the invention of gunpowder.*—Before we enter upon a description of the processes followed in the manufacture of gunpowder, it will be proper we should offer a few remarks relative to its history, which, like that of most important inventions, is somewhat obscure, the origin being attributed to different ages and to different nations.

The Chinese here, as in the invention of the mariner's compass, lay a claim to a knowledge of the art long anterior to that of any European nation, and this claim is admitted by the celebrated Lord Bacon, who says, "Certain it is, that ordnance was known in the city of Oxidrates in India, and that it was this which the Macedonians called thunder, lightning, and magic; and it is well known that ordnance had been in use in China for more than two thousand years."—Bacon's *Essay on the Vicissitude of Things*.

The Greeks also seem to have had some knowledge of explosive mixtures, but not of their application, for Salomoneus was said to be able to imitate thunder and lightning, which has been supposed by many to have been performed by means of the explosion of gunpowder or some such composition; indeed it appears from various authorities, according to the statement of Dr. Watson, that a knowledge of some explosive mix-

Plates for enamel painters.

Transparent enamelling.

History of gunpowder.

Early claims of the Chinese.

Of the Greeks.

Manufac-
tures.

ture of the nature of gunpowder was certainly known in very ancient times both in Greece and in Asia.

It is, however, a different sort of knowledge to be possessed of the secret of making highly explosive mixtures, and that of being able to apply that substance to the purposes of war, or to the more desirable purposes of peace and the Arts. Dr. Watson very properly observes, "There are substances in nature from a combustion of which it is possible to destroy a ship, a citadel, or an army, by a shower of liquid fire spontaneously lighted in the atmosphere; every person who is aware of the dreadful fiery explosions which attend the mixture of two or three quarts of spirits of turpentine with strong acid of nitre must acknowledge the truth of this assertion; but the simple knowledge of the possibility of effecting such destruction is very different from the knowledge of its practicability, although future ages may perhaps invent as many means of making these substances unite in air, so as to make them fall down in drops of fire, as the moderns have invented of making gunpowder the sad instrument of the destruction of our species."

Roger
Bacon.

The celebrated Roger Bacon, who died in Oxford in 1292, unquestionably possessed a knowledge of the present composition of gunpowder, but there is only a very vague expression of his to lead us to suppose that he was acquainted with a practical application of it either to war or to any other purpose, although it was certainly so applied soon after his death; nor does it follow that, because he was (as is very probable) the first Englishman who was in possession of this secret, that he was also the inventor of the composition. Dr. Watson remarks that it is very probable, as Bacon was skilled in the Arabian books and sciences, that he derived his knowledge of gunpowder from the same source from which he derived much of his optical science, *viz.*, from books brought over by the Moors into Spain a few years before his own time.

State of the
knowledge
of gunpow-
der in the
XIIIth
Century.

At all events, it is pretty clear that a knowledge of what we now call gunpowder was partially possessed both in Europe, Asia, and on the coast of Africa in the XIIIth Century, but up to that time it had never been employed in war by any of those nations. Had the Art of applying it been known at the time that Mahomet and his immediate followers were extending their destructive sway by means of the most bloody warfare, there can be no doubt (supposing the knowledge to have been possessed by the Arabs) it would have been had recourse to; and if it had been so employed, there can be as little doubt that it would have been recorded by Mahomedan writers, and made the subject of miracles without number.

Not applied
to war in
Europe
prior to 1300

From these circumstances, then, we may conclude that gunpowder was not known as an auxiliary in war during any part of the XIIth Century, but there seems as little doubt that it was so employed in the XIVth Century. The battle of Cressy was fought in the year 1346, and an historian who lived at the time is quoted by Spondanus as affirming, that the English greatly increased the confusion the French had been thrown into, by discharging upon them from their cannons hot iron bullets. Neither is this the first notice of the use of guns in battle, for, three years before the battle of Cressy, the Moors were besieged by the Spaniards in the city of Algeziras; and it is stated by Marina, a Spanish historian, "that the besiegers did great harm amongst the Christians with iron bullets they shot, and this," says the author, "is the first time

Battle of
Cressy

we find any mention of gunpowder and ball in our histories." The Earls of Derby and Salisbury are mentioned by the same author to have assisted at this siege, and, as they returned to England in 1343, it is not an improbable conjecture that, having been witness of the havoc occasioned by the Moorish fire-arms, they brought the secret from Spain to England, and introduced the use of artillery into the English army in the above celebrated battle.

About the same time the use of gunpowder was introduced into the armies of Germany and Denmark, and even the invention itself has been attributed to a German monk, Barthold Schwartz, but this claim, although very generally admitted, cannot be well grounded if what is stated above is to be, as there seems no reason to doubt it may be, considered authentic.

The statement of Schwartz being the inventor is made by father Kircher, with some particulars which gives to the story an appearance of fact, and to this is probably to be attributed the general credence which it obtained. He says that this monk, who was a learned alchemist, having mixed together, with a medical view, nitre, sulphur, and charcoal, a spark accidentally fell upon the mixture, blew up the pot in which it was contained, and caused a dreadful explosion. The monk, astonished at the event, made several repetitions of the experiment, and thereby fully discovered the nature of gunpowder in the year 1354; and the same author gives an account out of some old book he had read of the use he afterwards made of his discovery, *viz.*, by means of it frightening some robbers from their haunts in certain woods in his neighbourhood. Other historians, as Sebastian, Munster, Pontanus, a Dane, and Polydore Virgil, all agree in giving the invention to Schwartz, but the facts before stated are certainly at variance with it, and if the date upon an old gun can be received in evidence, it would appear that, even before the siege of Algeziras, ordnance was known in Germany, for it is mentioned in the *Acta Eruct.* 1769, p. 19 that in the armoury of Amburg, in Bavaria, there is a piece of ordnance on which is inscribed the date 1303. This, however, may be an antedate, and cannot be admitted as any material evidence.

Father
Kircher's
account of
the inven-
tion by
Schwartz,
1354.

There is another case quoted of an earlier date for the use of gunpowder, which appears, however, to be an error. A Danish historian, quoted by Camerarius, relates that Christopher, King of the Danes, was killed in battle by the stroke of a gun in the year 1280, which, if correct, would carry the invention back to the time of Roger Bacon; but it appears that Waldemar did not succeed to the crown of Denmark till the year 1332, and that his son Christopher was killed in a naval engagement several years afterwards, probably subsequently to the siege of Algeziras and the battle of Cressy.

(718.) *Gunpowder Manufacture.*—Having given the preceding concise sketch of this important substance, we shall now proceed to describe the processes followed in its manufacture.

Gunpowder is made by the combination of three materials, saltpetre, sulphur, and charcoal, and according to the practice of the Government works in the following proportions, *viz.*

Saltpetre by weight.....	75
Charcoal ditto.....	15
Sulphur ditto.....	10
Gunpowder.....	100

Manufac-
ture of gun-
powder.

Manufac-
tures.
Method of
refining the
saltpetre.

In England the saltpetre employed in the manufacture of this article is either that imported immediately from the East Indies, or that extracted from damaged gunpowder; in either way, however, it may be said that the East Indies furnish the whole supply of saltpetre for English consumption, as we have already stated under Saltpetre Works. This article as imported is refined by solution, filtration, evaporation, and crystallization, after which it is fused, taking care not to use too much heat, that there may not be any danger of decomposing the nitre; by this means it is not only rendered more pure, but the water of crystallization is more certainly got rid of. The principal object in refining the nitre is to get it free from the earths and salt with which it is combined in its *rough* or imported state, and which, by deliquescing, would render the gunpowder liable to injury by attracting moisture, and thereby decomposing the accurate mixture of the composition.

The sulphur.

The sulphur used in the Government works is generally imported from Sicily, but sometimes English stone brimstone is made use of. In either case it is refined by melting and skimming, and the most impure by sublimation.

Charcoal.

The charcoal formerly used in this manufacture was made by charring wood in the usual manner; this is called charring in pits, but it is now made as described under the head Charcoal. (Art. 600.)

Powder-mill.

The ingredients being prepared according to these methods, and mixed in the proportions above stated, after each has been separately ground to a fine powder, the mixture is in this state sent to the mill, which consists of two stones placed vertically, and running on a bed-stone, in a way similar to those described in the mortar-mill, oil-mill, &c. The composition is spread on the bed-stone and wetted with as small a quantity of water as will, together with the revolution and weight of the runners, bring it into a compact body, but not into a paste. After the stone-runners have made the proper number of revolutions over it, and it is in a fit state, it is taken off. The powder-mill, such as we have described, is generally worked either by wind, or water, or horses, being merely covered in by a few light boards, and only about 40 or 50 pounds of composition is worked at a time, as an explosion will sometimes happen from the runners and bed-stones coming in contact, or from other causes; and when such accidents do occur they would of course be more terrible, and extend the evil further in proportion to the quantity.

Corning house.

(719.) *Corning-house.*—The composition as taken from the mills is sent to the corning-house to be corned or grained. Here it is first pressed into a hard and firm body, broken afterwards into small lumps, and the powder then grained, by these lumps being put into sieves, in each of which is a flat circular piece of *lignum vitæ*. The sieves are made of parchment-skins, having round holes punched through them. Several of these are fixed in a frame, which by proper Machinery has such a motion given to it as to make the *lignum vitæ* in each sieve go round with a certain velocity, breaking the lumps of powder and forcing them through the sieves, and thereby forming grains of several sizes; the grains are then separated from the dust by proper sieves and reels. They are then hardened, and their rougher edges taken off by running them a sufficient time in a close reel which has a circular motion given to it. The powder for guns, mortars, and small arms, is generally made at the same

time, and always of the same composition; the difference being only in the size of the grains, which are separated by sieves of different degrees of fineness.

The gunpowder, thus corned, dusted, and reeled, (the latter being denominated glazing, as it puts a slight degree of gloss on it,) is sent to the stove and dried, keeping the heat down below what would be liable to decompose the sulphur, a proper thermometer being provided for the purpose.

The drying-house is either heated by steam or by what is called a *gloom*. The latter is a species of stove formed of a large cast-iron vessel projecting into one side of the room, which is heated from the outside. From the construction it is nearly impossible that fire or sparks can be thrown from it, and the powder is not removed from the house till the heat has subsided; the gloom is, moreover, furnished with a copper or other covering; still, however, one cannot feel the same degree of security in this mode of drying as in that by steam-pipes, which are certainly in every respect to be preferred.

(720.) *Improved mode of mixing, granulating, &c.*—The preceding is a concise view of the usual process of manufacturing gunpowder as generally followed in English works, but there are some minutiae connected with the mixing, corning, &c., which differ considerably under different makers, and on the precision of which much of the quality depends. Sir William Congreve, who was Director of the Laboratory of the Royal Arsenal at Woolwich, in 1815, took out a patent for certain Machinery to be employed for these purposes; the process, as described by the author, is exceedingly ingenious, and a concise account of it cannot fail to be interesting to the reader.

Machine for mixing the ingredients.—As it is highly important for the production of good gunpowder that the constituent parts should be uniformly mixed, too much care cannot be bestowed on this process, and the Machine we are about to describe seems well suited to this purpose. It consists of three hoppers for each of the three ingredients, fixed in one frame close together and in one line, and a cylindrical hair or wire brush, about three inches in diameter, and six or eight inches long, is fitted on an axis into an oblong aperture of the same dimensions in the bottom of each hopper. On this cylindrical brush the composition in the hopper lies, so that when the brush is made to revolve on its axis the composition is drawn out in a fine stream of the same breadth as the brush; and on the same principle as cotton-thread is drawn by the revolution of the rollers in the cotton-mill: the fineness of the stream being adjusted by the closeness with which the cylindrical brush is fitted to the aperture of the hopper. With this arrangement it follows that the quantity of composition drawn out in a given time depends upon the number of revolutions made by the rollers in that time, and consequently any required proportion of the different ingredients may be drawn from each hopper, according to the different velocities with which each of the brush-rollers are made to revolve; and these being regulated according to the due proportions required for gunpowder, and their motion being sustained and ensured by proper Machinery, the means are provided of keeping up these streams for any length of time required.

Thus far we see the uniformity with which the quantities of each ingredient are delivered; we have now to

Mechanical
Processes.

Drying or
gloom.

Improved
mode of
mixing.

Manufac-
tures.

explain the method adopted for uniting them into one heap. This is effected by a broad endless band which runs on rollers beneath and in a line with the hoppers and brushes, this band being kept in motion by the same Machinery which gives motion to the brushes; and on this band, so in motion, are received the three proportionate streams of composition above described as issuing from the three hoppers. In proportion, therefore, as the velocity of this band is increased, in respect to the velocity of the issuing streams, so will these streams be reduced in thickness, drawn out by this second process, and carried away upon the band in laminæ, thinner and more attenuated than as they issue from the hoppers. It follows, therefore, as the band passes with the same velocity under each of the hoppers, that it will be covered with a stratum of composition composed of the three ingredients, uniting upon the band in the due required proportions, and attenuated by a sufficient velocity in the band, so as to bring the falling particles of each ingredient into a due and almost mathematical juxtaposition with those of the other two, and in the predetermined proportions regulated by the velocities of the extracting rollers. It is almost needless to add that the combination of particles thus collected is detached from the band where it turns over the end roller, and is there gathered into a single receiver. In this way every mill-charge may be mixed separately, or in greater quantities, according to the size of the apparatus; and although the mixture thus obtained may be considered as nearly perfect, still, as a few small lumps will sometimes escape the revolving brushes, it has been considered advisable to pass the composition from this receiver through another Machine, for the purpose of breaking down any such irregularities, and for the more complete incorporation of the ingredients. This second Machine is somewhat similar, but consists of a single hopper only, having a large cylindrical brush at the bottom of it, the lower part of which acts against a fine wire sieve, embracing half the brush.

By this means the contents of the hopper, consisting of the compound of ingredients united as above described, are forcibly driven through the sieve, and reduced to the finest powder, so as, by a few repetitions of the process, completely to remove any imperfections that may remain after the first mixture. The repetition of this operation to any desired extent, in one continued process, is effected by letting the contents of the hopper fall into the inside of a vertical drum fitted with ledges. This drum works round the hopper, so that, when revolving, it carries the composition received from the hopper at the bottom round the top, and drops it back again into the hopper from the ledges as fast as it issues; and for as long a time, or as frequent repetitions of its passage through the brush and sieve, as may be wished, by keeping the Machine at work.

Such is the plan proposed by Sir William Congreve for mixing the ingredients, and it must be admitted to be exceedingly ingenious and effective; and as one of the principal objects of the mill is the due combination of the component parts, the latter process, it is said, may be considerably shortened, and it was the opinion of the inventor that it might probably by this means be wholly dispensed with. We must, however, suppose that it passes from the last mixing Machine to the mill, and there undergoes the process already described, and thence to the press.

Press-house. (721.) *Press-house*.—The alteration made here is that,

instead of the coarse mode of throwing the mill-cake under the press as it comes from the mill, leaving considerable intervals in the mass, and forming thereby a soft and brittle cake in the parts near these intervals, the mill-cake is now broken down by passing it through brass rollers with coarse teeth, by which it is so reduced that it may be distributed very regularly, and the cake produced becomes thereby of a more uniform consistence; moreover, the cakes are thus formed much thinner than in the common way: that is to say, instead of being $2\frac{1}{2}$ or 3 inches thick, they are made here, by using a greater number of copper-plates, into cakes of only $\frac{1}{8}$ of an inch thick, and thus are more fitted for the next operation of granulating, which process is also performed by a new Machine.

(722.) *Granulating Machine*.—This consists of three parts in three distinct rooms, one principal, and two other adjoining small rooms, lightly covered in, having a strong brick wall between them to act as a traverse to each; in the principal or middle room of the three the actual granulating apparatus is placed.

In the first of the adjoining rooms is contained a large hopper, in which the pressed cake is deposited, in quantity not exceeding a barrel at a time, to supply the Machine in the second or middle room; while the third room contains a bin into which the powder passes as fast as it is granulated in the second, and is thence carried away, at stated periods, to a magazine, to prevent any accumulation in the granulating-house.

The granulating Machine, in the middle room, consists of two sets or pairs of brass rollers, about two feet six inches in length and two inches in diameter, supported in the middle, and divided into teeth, each pair working together by means of a pinion or nut at the end of each roller, so that they draw inwardly, like the rollers of a flattening-mill, or those of a cotton-mill.

The teeth of these two sets of rollers are of different degrees of fineness, and the rollers are set at different distances; the coarsest so far apart as readily to draw in the thin pressed cake above described. These pairs of rollers are set in a strong frame of cast-iron or wood, about six feet high and eight or ten feet long, more or less; so that the upper and coarser pair are at the top of the frame, about eighteen inches or two feet higher than the other pair. They are then connected either by a double crank, or by a rod and pinion, or in any other way, so that when one pair is set in motion by the principal mover of the Machine, whatever it may be, water, or horse, or any other power, the other pair will also move; and they are, moreover, so arranged, whether in a direct position over one another or obliquely placed, that whatever passes through the upper or coarser pair shall pass also through the finer or lower pair; the teeth of the coarse pair of rollers are so constructed, that the thin press-cake being brought gradually into a hopper surmounting those rollers, is immediately drawn through them, and broken into irregular fragments or heads; which fragments, again passing through the lower or finer rollers, are finally and at once reduced into perfect grains of every different size required; which are separated in one operation by falling from the lower pair of rollers upon a series of wire sieves, calculated according to the different sorts required. These sieves being of a sufficient length, from four to six feet, are placed obliquely, and kept in motion by the common mover, so that the different grains pass from top to bottom of these sieves in the act of separation, which, at the same time,

Mechanical
Processes.

Granu-
lating Ma-
chine.

Manufactures.

cleanses the powder from the dust. These different sorts of powder and their dust, having thus been separated and carried to the bottom of the sieves by their motion and obliquity, are, from each respective sieve, delivered into a flat funnel, which disposes of each sort upon a horizontal endless band of canvass, or other material, running from the foot of the granulating Machine in a flat trunk through the traverse wall into the bin above-mentioned, as being provided in one of the adjoining rooms for receiving the powder when granulated; there being as many bands and as many compartments in the bin as sorts of powder, including the dust, and these bands being kept in constant motion by the first mover, so as to carry off every grain of powder and dust as fast as it is formed, and thereby prevent any accumulation about the Machine in the act of granulation.

Method of feeding the Machine.

It remains now only to describe how the Machine is fed with cake, that also being done by a mechanical process, to prevent the necessity of any person being near when actually at work. This is, in fact, performed by nearly the same operation as that by which the powder is carried off after it is grained, that is to say, by bands of canvass, or any other suitable material, passing from the hopper in the outer room, through the traverse wall, into the hopper over the upper set of granulating rollers, in the middle room; these bands, however, are stronger, more tightly strained, and have straps of leather, or cords, or small rods sewed flat upon them every nine or ten inches, to raise the cake out of the hoppers, the back of which being placed at an angle of forty-five degrees of inclination, and the band moving up that back, the cake, although thrown *indiscriminately* into the hopper, is, nevertheless, drawn out of it in single pieces, lying flat upon the band, any surplus, not actually raised and supported by the cross straps on the band, falling or sliding back from the great inclination at which the strap moves in its progress up the back of the hopper. Having surmounted this, however, with its due load, namely, covered with a single layer of cake, the band takes a horizontal course through the traverse wall, until it reaches the edge of the hopper of the granulating Machine, and there discharges its load in regular quantities between the upper set of rollers for granulating, as already stated.

It is almost needless to say, the only remaining detail of the Machinery necessary to be described is the form of the teeth of the rollers: they are of various sorts, either grooved horizontally, so as to bring the teeth to sharp or spiral grooves, and, either cross-cut or not, into rings, leaving void spaces between them, equal in breadth to the rings of the teeth themselves, and so arranged on the reciprocal rollers, that the rings of the teeth on one roller shall work in the void spaces of the other, and *vice versa*, but no part of the rollers or teeth actually touching in any case; thus arranged the teeth never clog. Here also it must be stated that the edges of the large rollers in the press-house, for breaking down and preparing the mill-cake, are formed on similar principles to those of the granulating rollers, only coarser in proportion as the mill-cake is thicker than the press-cake.

These granulating Machines have several advantages; in the first place, the whole operation being, as above described, performed by mechanical means, requires no person to be present in either of the rooms, except at the moment of the discharging the powder from the

bin, and of replacing the cake in the hopper, which is performed at the same time during which the Machine is stopped; and, moreover, as no accumulation can take place in any part, it follows that there is no personal danger to any one, neither can any serious mischief happen to the Machine itself with the traverse walls, if the quantity of cake put in at each charge be limited, as above stated, to a barrel at a time; the small quantity which can ever exist in the principal room protects the Machine itself, while the adjoining buildings being of a slight and temporary nature, an explosion with the quantity limited would be of little consequence, no person being, as before stated, required in the building when the work is going on. The Machine above described was found competent to manufacture six barrels of gunpowder per hour.

Mechanical Processes.

(723.) *Qualities of different gunpowders.*—The preceding description of the Machine invented by Sir William Congreve is given principally from a short Treatise by the inventor, published in 1815, on the process of making gunpowder, and it must be admitted to be exceedingly ingenious and that it is attended with considerable advantages; but the inventor, perhaps, rates these too highly in some parts of his account, which, therefore, we have not noticed. With respect to the advantage of such accurate mixing there can be no reasonable doubt, but that the most accurate mixing will ever supersede the mill-work is contrary to the opinion of those who are best qualified to judge on this subject. In vol. ix. of the *Phil. Mag.* a Paper is given by Mr. Coleman, of the Waltham Abbey Powder Works, descriptive of the general process at that time followed, to which we have been indebted for several particulars in the leading part of this notice. We propose also, in conclusion, to state the results of several experiments by the same gentleman on the qualities of gunpowder as depending on different modes of mixing, proportionate strength, specific gravity, &c., most of the experiments having been from large quantities of powder made in the above Works.

Qualities of gunpowder.

Results of Experiments.

1. One hundred parts of composition gain from three to four or five parts in weight by the water used at the mill.
2. This water appears to be totally got rid of by the succeeding processes of manufacturing and stoving, and, therefore, it follows that the aqueous matter in gunpowder is only what is at first contained in the ingredients.
3. The ingredients, only pulverized and mixed, have a very explosive force.
4. Gunpowder granulated after having been but a short time in the mill has only acquired a portion of its strength.
5. It is not till it has been the proper time in the mill, and been properly made there, that it has obtained its full power.
6. The strength of gunpowder does not depend on the granulation, the dust of gunpowder, after manufacture, having nearly the same force as when granulated.
7. Powder made in every respect the same, but of two sorts of charcoal; *viz.* pit and cylinder, is very different in strength, the cylinder charcoal rendering the gunpowder made therewith much superior to that made with pit-charcoal.

Experimental deductions.

Manufac-
tures.

8. Powder undried, in every stage of manufacture, is weaker than when dried.

If the composition on a mill explodes by any accidental cause, shortly after it has been put on the stones, it goes off with a very slight explosive force, principally in flame; but if it has been an hour or two under the runners, and then explodes, it more or less destroys the mill, throwing the boards of the covering and sides to a considerable distance.

The specific gravity of gunpowder is differently stated by different authors. Count Rumford makes that of solid gunpowder 1868, and of loose but well shaken gunpowder 1077; but Mr. Coleman states that from repeated trials he found that the density of powder varies considerably from different causes in the manufacturing; for which reason, he says, no exact specific number can be assigned to it, but he has no doubt the above numbers of Rumford are the greatest it will ever attain. The author says he has frequently seen it less than that of water.

Causes of
the explo-
sive pro-
perty.

(724.) *On the cause of the explosive quality of gunpowder.*—The following deductions are founded on the preceding experimental results by Mr. Coleman, which he states as below.

1. That the explosive force of gunpowder depends very materially on the carbon employed. This he conceives to be borne out by his experimental result 7.

2. That the mixture only of the ingredients without milling does not make that necessary incorporation of the parts for proper combustion, and for the full explosive effect. Experimental results 3, 4, 5, 6 are supposed to bear out this conclusion.

3. That the less moisture there is in gunpowder, the stronger is its effects. This is clear, from gunpowder which has attracted any degree of humidity being weaker than when first made.

After the above statements and deductions Mr. Coleman observes: "I shall now beg to submit some ideas that occur to me from a consideration of the whole of the circumstances I have related, and from what may be deduced from an examination of the component parts of gunpowder. It appears to me that no part of the explosive force consists in elastic vapour, formed by the combustion, from water contained in it. So small a portion of water is in the ingredients, and I have observed that not any is gained in the manufacturing, that I cannot conceive any water is carried off undecomposed, but that it is converted into hydrogen and oxygen gases. Mr. Cruickshank observes, after the explosion of gunpowder over mercury no water is seen. I am of opinion that the explosive force of gunpowder consists wholly in the several gases formed by the combustion; and that the quicker it takes fire, the more gas is generated in a given time, and its force consequently greater. Lavoisier observes, its effect is increased by the quantity of caloric disengaged at the moment of deflagration."

It seems, therefore, that the combustion is carried on by the oxygen supplied from the nitre; that this gas is instantly taken up by the sulphur and carbon; and, converting those substances into carbonic and sulphuric acid gases, azotic gas being at the same time liberated from the nitre, the water which may be in the nitre, and also that which is in the charcoal, is decomposed; and the oxygen taken up by the carbon and sulphur, and the hydrogen set free. The force arising from these gases, with the increased elasticity they

receive from the increase of temperature caused by the combustion, is surely sufficient to account for the effects we observe in gunpowder.

Mechanical
Processes.

It may probably serve to elucidate the subject, if we consider a little minutely what the component parts of gunpowder are from chemical analysis.

Nitre.—100 parts of nitre, according to Kirwan, consist of

Potash	51.8	} dried in a heat of 70°.
Acid	44.0	
Water of composition	4.2	

By several experiments the author found that nitre, which had been dried at 70°, loses 3 per cent. in melting.

Lavoisier says, 100 parts nitre consist of

Potash 49, dry acid 51, and that this dry acid is	
Oxygen	40.6
Azote	10.4

Charcoal, according to the same Chemist, absorbs 2.5714 of oxygen in combustion. From various experiments made by Mr. Coleman he had reason to conclude, that charcoal, when used, contains about $\frac{1}{8}$ th of water which it has absorbed.

Sulphur, according to Berthollet, requires for every hundred parts 36.8 oxygen to form sulphuric acid; of course a small quantity of oxygen would be necessary for their conversion into sulphuric acid gas; taking this at 30 per cent., which is probably not far from the truth, and admitting this, the following will turn out to be the quantities of the constituent principles which enter into the composition of gunpowder.

75 parts of nitre, containing.	{ Dry nitre...	74.25
	{ Water	0.75
15 parts charcoal.	{ Carbon	13.13
	{ Water	1.87
10 parts sulphur.....	Sulphur	10.00
		100.00

And these again contain

Nitre 75 =	{ Potash .. 36.75	Char- coal {	Oxygen . 1.60
	{ Oxygen .. 30.34		Hydrogen 0.27
	{ Azote ... 7.80		Carbon . 13.13
	{ Hydrogen 0.11		
			75.00

Whence 100 parts gunpowder consist of

Potash	36.75
Carbon	13.13
Sulphur	10.00
Oxygen	31.94
Azote	7.8
Hydrogen	0.38
	100.00

We know that all the charcoal is not consumed in the act of combustion. Mr. Cruickshank states, that 3 parts remain of 100 equal parts of gunpowder, therefore 10.13 parts are destroyed. Now,

10.13 parts of carbon absorb ..	26.05	of oxygen.
10 parts of sulphur absorb	3.00	ditto.

Oxygen used	29.05
Oxygen in the ingredients	31.95

Surplus of oxygen

2.90

It is clear the smallest error in the quantity of charcoal used will easily account for this difference of oxygen.

Manufac-
tures.

On the above calculation it seems the quantity of each ingredient is pretty well regulated, and that the gases formed will be expended in producing the effects we observe in the combustion of gunpowder.

Residuum
of fired
gunpowder.

The residuum of fired gunpowder Mr. Howard thinks to be an alkaline sulphuret mixed with carbonate and sulphate of potash. But by several trials made by Mr. Coleman, he found reason to be of opinion, with Mr. Cruickshanks, that this residuum is very deliquescent, and when exposed to the air absorbs moisture sufficient to dissolve a part of the alkali; and in consequence the charcoal becomes exposed, and the whole assumes a dark or black colour, and this residuum is potash united with a small proportion of carbonic acid and sulphate of potash, a very small quantity of sulphurate of potash and unconsumed charcoal, and that 100 grains of gunpowder yield 53 grains, of which three are charcoal. *Phil. Mag.* vol. ix.

Sugar Works.

Sugar
works.

(725.) Before entering into a description of the culture and manufacture of this important article of commerce, it may not be uninteresting to the reader to trace the origin of this valuable plant, and briefly to sketch its progress from the first discovery until it has attained its present importance, not only with respect to the immense capital which it employs and the extent of public revenue which it yields, but as an article become necessary to the comforts of mankind.

For the following history of the sugar plant we are indebted to Mr. Potter, who has lately published a very valuable Work, entitled *Practical Directions for the Culture of the Sugar Cane, and for the Manufacture of its Products*. The author has collected with much labour all the facts relating to this subject, and enters into it at considerable length.

History of
sugar.

The Chinese appear to have been the first people who discovered the properties of the sugar-cane; and it is tolerably well ascertained that the inhabitants of that Country enjoyed its use some centuries before it was known and adopted in Europe. There is no mention made of it in the History of Ancient Egypt, Phœnicia, or Judea, and the Greek Physicians are the first who have spoken of it under the name of Indian salt, which, from the sweet taste and other characteristics assigned to it by Dioscorides and Pliny, without doubt was the same material which we now denominate sugar-candy.

Indian salt was brought to Greece and Rome from Arabia and India within the Ganges, but it was not cultivated or manufactured in those Countries. The cane at that time grew only in the Islands of the Indian Archipelago, in the Kingdoms of Bengal, Siam, &c., and the sugar that was produced from it passed with perfumery and spices, and other merchandise, to the Countries on this side of the Ganges. It found its way into Arabia in the XIIIth Century, the period at which merchants first began to visit India, and to traffic in the Indian articles of commerce. If the cane had been the produce of that part of Asia which lies between the Ganges and the Mediterranean Sea, or of Arabia or Africa, this plant, which grows so easily in all warm Countries, and which reproduces itself without culture, would certainly not have escaped the observation of the different Tribes who inhabited and roamed over every part of these Countries.

Marco Paulo, a noble Venetian, was the first European who visited the Countries in which the cane actually grew. He found that Bengal produced spices, ginger, and sugar in great abundance, and, upon the whole, gave so favourable an account of the Country, that the merchants who had formerly gone to Ormus, for the purpose of trafficking with the Indians, now directed their steps to Bengal itself.

Mechanical
Processes.

The precise period after the voyage of Marco Paulo at which sugar was first introduced into Egypt does not appear; we are only able to ascertain that at the end of the XIVth Century the cultivation of the sugar-cane, and the manufacture of its juice, were practised generally throughout Arabia, Egypt, and several other parts of Africa; and the testimony of various travellers, particularly that of Giovanni Leoni, proves that in the XVIth Century an extensive trade in sugar was carried on in Arabia Felix, Nubia, Egypt, Morocco, and Ethiopia.

In 1420, when the Island of Madeira was discovered by the Regent of Portugal, he introduced the sugar-cane from Sicily. It was cultivated with success there as well as in the Canaries, and soon after the sugar of these Islands, particularly Madeira, was greatly preferred to that of any other Country.

The Portuguese began the cultivation of the cane in the Island of St. Thomas (under the Line) immediately on its discovery; and we are told, on the authority of a Portuguese pilot, that in 1520 this colony had more than 60 sugar manufactories. The rich inhabitants had 200 or 300 Negroes employed in their plantations, and there were made on the Island 150,000 arobes (4,650,000 pounds) of sugar.

Soon after Columbus discovered the New World, one Pierre d'Etienne took the sugar-cane to Hispaniola, since called St. Domingo, and now Hayti. A Catalanian, named Michel Ballestro, was the first who expressed the juice from it, and Gonzales de Velosa the first who concentrated this into sugar. The latter built a mill on the river Nigua, and at his own expense sent for workmen from the Island of Palms (one of the Canaries) to manufacture the sugar. Sloane relates, on the authority of Martyr, that the cane flourished extremely well in St. Domingo, that it grew to the size of a man's wrist, and that the same root produced 20 or 30 shoots; while from those of Valance there were only 5 or 6. He says, also, that there were in 1518 28 manufactories on that Island. The cultivation of the sugar-cane in St. Domingo certainly extended with very great rapidity, and the produce was so considerable, that we are told the cost of the magnificent palaces of Madrid and Toledo, which were erected in the reign of Charles V., were entirely defrayed by the proceeds of the port duties on the sugar imported from Hispaniola.

Sugar-cane
first intro-
duced into
America.

Father Labat fixes the period of the first establishment of sugar plantations, by the Spanish and Portuguese settlers in America, at the end of the year 1580; but he must certainly, Mr. Potter remarks, be in error, since it appears that, in 1518, there were 28 plantations in St. Domingo alone.

Labat also asserts, on the authority of unknown and obscure travellers, that the sugar-cane is indigenous to America; but this appears to be without sufficient foundation, and is contradicted by the testimony of the most credible travellers. It is certainly mentioned by Captain Cook among the articles which the natives of the Pacific

Manufac-
tures.

West
Indies.

Islands brought to his ship, but we have not the slightest evidence to show that it is indigenous to the colonies of America; on the contrary, there is every presumptive evidence to disprove it.

In 1641 sugar-canes were transplanted from Brazil to Barbadoes, and thence to our other West India Islands. But the sugar made in Barbadoes was at first so bad, that it was considered scarcely worth sending to England, being full of molasses. In 1650 it had become much better in quality, but even then could not compete with that made in Brazil. Sugar was made by the English in the Island of St. Christopher in 1643; by the French at Guadaloupe in 1657. When Jamaica was taken from the Spaniards by the English, there were only three small sugar plantations on it, which were very soon much improved and increased.

Having now traced the steps by which the sugar-cane was introduced into the different parts of the New World, we shall endeavour to describe the progress which has taken place during that period in the process of the manufacture.

The Art of crystallizing sugar, as pursued by the Chinese, was in accordance with the soundest principles of Chemistry. It is thus described by Rumphius: "The expressed juice," says he, "is received into large boilers, placed over brisk fires; as the juice evaporates more is added, till it becomes red and thick; then it is put into deep earthen vessels, which are taken to a warm place. The sugar at the surface forms crystals, which are united in white clusters, called cakes of sugar, and that which crystallizes underneath is called Muscovado. The sugar is refined by being clarified in large boilers with whites of eggs; a little chicken fat is used in the operation; it is afterwards put into large earthen plates to crystallize. That which is obtained from cakes of sugar is very white and hard, resembling crystal; it is called *male sugar*: that which is obtained from Muscovado, the crystals of which are sweeter, and less hard and fine, is named *female sugar*."

Rumphius does not speak of the use of lime or other alkalis in evaporating the juice or refining the sugar: hence we may conclude that the Chinese and Indians did not use them, or this naturalist, whose accuracy is so well known, would not have omitted to mention the fact. It appears, then, certain, from the form in which sugar first came into Europe, as described by Dioscorides and Pliny, and from the state of that which Barthema and Barbossa found in the Indies, that the art of extracting the sugar, and of refining it, consisted among the Chinese in obtaining it in the greatest purity, under the regular crystalline form, such as it is in the state of sugar-candy. Rumphius says, "The Art of manufacturing the juice of the sugar-cane is not very ancient among the Indians; they either learnt it from the Chinese, or the desire of gain stimulated them to its discovery. Even now the Chinese are the only people who refine sugar in Java, and we can hardly doubt that the different Arts required in the cultivation of the plant, and the manufacture of sugar for domestic uses, were known by the Chinese from the highest antiquity."

The method employed in Arabia and Egypt to clarify the cane juice seems to be unknown; but it is very evident, by the foul and black sugar in which these Countries traded, that they followed plans quite different from those of the Chinese. The merchants who introduced the cane from India certainly neglected to bring

also the necessary instructions as to the methods of preparing the juice; and the difficulties which the Arabian cultivators experience doubtless caused them to try the use of all kinds of ingredients for its purification, and probably to invent conical vessels for crystallizing and cleansing the sugar.

The Venetians introduced sugar-refining into Europe at the end of the XVth Century. At first they imitated the Chinese, and sold the sugar which they purified in the shape of candy, clearing and refining the coarse sugar of Egypt three or four times over: they afterwards adopted the use of cones, and sold refined sugar in the loaf.

Sugar-refineries were soon established in all the commercial cities of Europe, and multiplied with wonderful rapidity, so that this article, which but a few centuries before was unknown to the people of the Continent, soon became one of the most important articles of commerce. It is unnecessary to describe the methods employed at that time for refining sugar; they were very various, and, from the want of that aid which the advancement of the Science of Chemistry has afforded to our modern refiners, were not conducted upon any fixed principle, and a great portion of the saccharine properties of the juice was wasted or destroyed during the operation.

Culture of Sugar.

(726.) The plant from which the sugar is obtained is known to Botanists by the name *Saccharum officinarum*, and is a genus of the *triandria digynia* class. Its characters are these: leaves flat, entire, smooth; panicle loose, with long, simple, slightly zigzag strokes; flowers in pairs, one of them stalked; calyx lanceolate, naked, except at the base; corolla awned. The stem, or cane, is one or two inches in diameter, with frequent joints; leaves from one to three inches broad.

Dutrone states the period of the sugar-cane arriving at full maturity to be from twelve to twenty months; but he was unacquainted with the Otaheitan variety, which was introduced into the West Indies about the end of the last and beginning of the present centuries. This is much larger and finer than the Brazil cane, and comes to maturity in about ten months in the elevated parts of the older settlements of the West India Islands; but in vales, and in the low alluvial soils of the colonies, where the land has not been much cropped, the plant is oftener from twelve to sixteen months, and even longer, in becoming fully ripe.

The cane plant is produced by the development of buds of a slip put into the earth, and this slip generally comprehends the top part, stripped of its leaves, and the two or three upper joints of the cane. Mr. Potter recommends holes to be made from fifteen to eighteen inches square, and about eight, ten, or twelve inches deep. These holes are made about two feet apart from each other in rows which are three feet distant, but this depends very much upon the soil, and the practice is not uniform throughout the Islands. The rows should be marked out by a line, and the ground divided into pieces about seventy feet broad, for the convenience of carting. The hole is banked up round its margin with the earth thrown up by the hoe, and manure is put into it. Two or more cuttings are then laid longitudinally in each hole, and at first these are covered with earth to the depth of one or two inches. The plant is thus placed in the most favourable state

the sugar-
cane.

Manufac-
tures.

for receiving and retaining the water acquired either from rain or irrigation; the loose state of the earth allows the roots to penetrate and spread with facility, while these numerous and spreading roots supply in great abundance the moisture necessary for the vegetation of the plants.

The soil generally acknowledged to be most favourable to the growth of the cane is a mixture of clay and sand; and although the effects of the rain on this soil are apparently soon over, its surface quickly drying, the inner portion retains a considerable degree of moisture even in the driest weather, and it has the advantage of seldom requiring trenches to be made even in wet seasons. Plant-canes in this soil, Mr. Edwards states, have been known in very fine seasons to yield $2\frac{1}{2}$ tons of sugar per acre. This soil very much predominates in St. Domingo; but in Jamaica is confined to particular districts, and even to particular spots.

Black mould of great varieties is also favourable for the production of the cane: the best is found in Barbadoes, Antigua, and some other of the West India Islands; but there is a species of this mould in Jamaica little inferior to it, which abounds with limestone and flint on a sub-stratum of soapy marl. Black mould on clay is more common, but it is generally only in a very thin stratum, and the clay is tenacious, and retentive of water; this last sort of land, in consequence, requires great labour, both in ploughing and trenching, to render it profitable; but properly pulverized and manured it becomes extremely productive.

Canes will not flourish on mere sandy soil; to make them grow there requires a great expense for manure, as well as frequent rains, or the command of water for irrigation.

A proper attention to the manuring of land is of the greatest importance to the sugar-planter. Mr. Potter remarks: "When land is unproductive we should inquire into the cause of its sterility, which must necessarily result from some defect in the constitution of the soil; some lands of apparently good texture are yet extremely barren, in which cases the cause can only be ascertained by Chemical analysis. By this means the noxious principle which exists will easily be discovered, and most probably easily destroyed. If any of the salts of iron be found present, they may be decomposed by lime. If any inert vegetable matter be indicated, this may be removed by lime, paring, and burning. If there be a deficiency of vegetable matter, it may be supplied by manure; and if there be an excess of silicious sand, a mixture of marl will tend to correct it.

"In stiff heavy soils chalk and sea-shells are used with great advantage. Low swampy grounds, besides the assistance of lime, chalk, or sand, should be well drained, and every facility given for the escape of stagnant waters, and the overplus of those which collect after storms; the land should be divided by wide ditches into parallelograms, or beds, the drains being from ten to one hundred feet apart, according to the degree of moisture of the earth; and each of these beds should be raised in the middle, gradually sloping towards the ditches.

"Lime is beneficial to almost every soil, and especially where the salts of iron are found; but where carbonate of lime already exists in the soil, lime and chalk are, of course, useless, inasmuch as there is little or no undissolved vegetable matter."

The manure generally used in sugar-planting is a

compost formed, first, of coal and vegetable ashes, drawn from the fires of the boiling and still-houses; second, feculences discharged from the still-house, mixed up with the rubbish of buildings, &c. &c.; third, refuse, or field-trash, that is, the decayed leaves and stems of the canes; fourth, dung obtained from the horse and mule-stables, and from fixed and movable pens; fifth, good moulds collected from ravines, gulleys, and other waste places.

The first is supposed to be a manure in itself for cold and stiff clays, and it is the custom in some places in which this soil is found to carry ashes out in Autumn, and, when the land is holed, a quantity of about fifteen or twenty pounds is put into each hole, and mixed with the mould, at the time the plants are put into the ground.

Between August and November is generally considered the best time for planting; the young canes nourished by the rain then become sufficiently luxuriant to shade the ground before the dry weather sets in, thus keeping the roots cool, and the earth around them moist. The season for planting, however, depends so much on local peculiarities in different Countries, that no general rule can be given. Cazaud, who appears to have had much practical experience, recommends May and June as the most advantageous period for planting. After employing the first six months of the year in the business of the crop, he then plants the land from which the canes were cut in January, and only plants one-sixth part of his land every year, leaving the rest for rattoons (or the canes proceeding from the old stumps.) He cuts his whole plantation every year, and thus both his plants and rattoons are cut at eleven months' growth.

Mr. Cazaud has largely illustrated the reasons and advantages of this method, the fundamental principle of which is the necessity of planting the canes in the only season fitted to accelerate and preserve them, the weather in the Windward Islands being commonly dry from the 15th of February to the 15th of May: from that time the rain is moderate until August, increasing to November, then decreasing till February, and thus the progression of the rain keeps pace with that of the cane, when planted in May. The maturity of the cane, as regards its essential salt, he asserts does not depend upon its age, but upon the season; canes, whatever their age may be, being as ripe in February, March, and April as the nature of the soil ever allows them to be.

Another system is also advantageously followed in some situations, which consists in planting in August and September, and allowing the plants to proceed as usual until January, when the young plants are cut close to the ground with knives, and the remainder spread on the ground over the roots, which soon afterwards send forth a number of vigorous luxuriant shoots, all of equal growth. It is said that by these means the canes are not too rank in the stormy months, while they come to perfection in good time in the succeeding Spring.

On some soils it is found better to depend chiefly on ratoon canes, by which means the produce of sugar per acre, if not equal to that from fresh plants, yields, perhaps, on the long run, quite as much profit to the owner, if the relative proportion of the labour and expense attending the two methods be taken into consideration.

The general practice is to plant about one-third of the cane-lands every year, which, of course, imposes a great

Mechanical
Processes.

Manufac-
tures.

toil on the Negroes, from which they are very much relieved when the planter trusts to rattcons for his sugar, in which case, instead of the excessive labour of holing and planting anew, the roots are allowed to continue in the ground, and as they become thin and impoverished, the vacant spaces are supplied with fresh plants. Mr. Potter recommends that the earth round the roots should be loosened, and cleared from weeds; and in the older settled colonies, as soon as the ground has been refreshed by rains, that the roots should have manure placed round them, which being covered with cane-trash, to prevent its virtues being dried up by the sun, is found at the end of three or four months to be soaked into and incorporated with the mould. At this period the rattcons should again be well dressed, after which very little care is requisite until the canes are fit for cutting.

If the soil is favourable to the vegetation of canes, and the land is carefully managed, the same plantation may continue twenty years without replanting, and give good crops the whole of the time; but in the common method of planting the lands are sometimes replanted every six years, but those which are poor are only continued for two or three years.

The produce of sugar-plantations is sometimes completely destroyed by a disease termed the blast, which consists of myriads of little insects, invisible to the naked eye, which feed upon the juice of the cane, in search of which they wound, and consequently destroy, the vessels; the circulation is thus impeded, and the growth of the plant is checked in proportion to the degree of the ravage. It is said that the blast never attacks those plantations where colonies have been introduced of the little animal called the carnivorous ant, the *Formica omnivora* of Linnæus, and the *Raffles* of Jamaica. Several other species of insects are also destructive to the sugar-plant. In some of the Windward Islands a kind of grub, called the Borer, *Calandra sacchari*, in very dry weather commits depredations on the cane. This insect was found fatally destructive in Guadaloupe in the years 1785 and 1786.

The Rev. Lansdown Guilding, of the Island of St. Vincent, received from the Society of Arts, in the year 1827, the gold medal for a Memoir on the insects which infest the sugar-cane in the West Indies. He states, "that by far the most common enemy is the smaller grub of the moth; these in some of the colonies, which, from the absence of mountains, or other causes, are subject to dry seasons, have been known to blast the hopes of the year, to destroy whole acres of canes, and ruin the unfortunate planter."

The object of the planter should be to prevent the insects from depositing eggs in the plants rather than to kill those which have already begun their operations; and Mr. Guilding has found from long-continued experiments that they may be almost entirely expelled from any quarter in which canes are carefully stripped of dry and useless leaves, under which, as they become loose, the female borer deposits her eggs. It is well known that the vaginating leaves of the cane hold for a long time the water which has been collected in them during rains, from which, in dry weather, the plant may doubtless derive nourishment. In the drier Islands the planter will probably object to the only plan which seems capable of lessening the number of his foes, under the idea that he will expose the plants too much to the

merciless rays of the sun, but Mr. Guilding does not recommend that a single leaf should be taken off except those which are withered, and incapable of holding water for the refreshment of the plant.

The borers are found to be much more fatal to the plants than to the ratoon canes, which should, of course, be oftener visited by the Negroes, whose business it is to collect the trash. A single cane will sometimes nourish several of the borer-worms, which perforate every joint, when the centre becomes discoloured and sour, not only yielding nothing at the mill, but communicating a dark colour and bad quality to the syrup of the sounder plants. It in consequence becomes very necessary, when the canes are cut, that those which are in any way damaged should be sorted from the rest, and not on any account sent to the mill.

The canes should be cut as nearly as possible to the ground, which will give new vigour to the rattcons that spring from the old root, while the juice from these lower joints is the richest the cane contains. It may, perhaps, be sufficient to cut off only one joint of the cane with the top from those canes which grow on very dry soils; but otherwise two should be cut, for if they be not sufficiently watered their juice will only injure the sugar, instead of augmenting its quantity.

The canes being cut are tied into bundles for the convenience of taking them to the mill. On the mountains they are carried by mules. In some parts the bundles are rolled down steep places, or passed down wooden spouts. In the plains they are conveyed in small carts, drawn by oxen or mules, to enclosures near the mills; and in Guiana in flat-bottomed punts or boats, through navigable trenches, which intersect the plantations for the purpose.

Sugar-mills.

(727.) The mill employed to press out the juice from the sugar-cane is very simple in its construction, consisting of three rollers, of about 20 or 25 inches diameter, and from 30 to 40 inches in length. Between these rollers the canes previously cut are twice compressed by passing them through the first and second roller, and afterwards forcing them round, either by hand or by a circular piece of framework, called in Jamaica the *dumb returner*, so as to pass through the second and third,—an operation which squeezes them perfectly dry, and sometimes even reduces them to powder. The rollers were formerly constructed of wood, covered with steel or iron plates, but are now generally made of cast-iron, with flutes or grooves cast in them, which are found to work more truly, and to be less liable to get out of order.

Sugar-mills are worked by cattle, wind, or streams of water, and latterly a great number of steam-engines have been sent out to the West India plantations. In situations where a fall of water can be obtained water-mills are preferable to either cattle or windmills; for if cattle are used, an extra stock must be kept on purpose, because the regular cattle of the plantation are fully employed at this season of cutting out the canes. The operations of the mill should be carried on regularly, so that the canes are ground as fast as they are brought from the fields; otherwise there is danger of their juice fermenting. For this reason windmills are very objectionable, as no dependence can be placed on them for fulfilling their allotted task in the required time.

Processes.

Sugar-mills
described.

Manufac-
tures.

In many windmills levers are provided, to which mules or oxen can be harnessed to work the mill when the wind fails, the Machinery of the sails being at the same time detached; but this expedient takes off the cattle from their regular employment, which is a considerable inconvenience. A water-mill or steam-engine is free from these objections; and, if it is sufficiently powerful, the whole produce of a plantation can be pressed, and the juice obtained ready for the boiling-house, in so short a time that the juice will be quite fresh. There are some water-mills in Jamaica sufficiently powerful to grind as many canes in a week as will make thirty hogsheads of sugar.

Until a comparatively recent period the cylinders or rollers were placed in a vertical position, and in a line with each other, which arrangement is still very generally adhered to. In this description of mill the rollers are mounted in an iron frame consisting of two horizontal frames, sustained by uprights, and the openings of the frames contain the brass bearings for the pivots of the three rollers, which brasses are adjustable by means of cross keys and wedges driven through the opening, so as to force the rollers towards each other, and retain them at a regular and invariable distance. The surfaces of the rollers are fluted with grooves of a small depth, which enables them to take a firmer hold of the canes, and also facilitates the running down of the juice into a pan or cistern formed round them at the lower part, at one end of which there is a spout to carry off the juice into a pipe which leads to the boiling-house. This receptacle for the juice forms a small circular channel or gutter round the roller, and has a raised rim carried round the centre part or pivot, the edge of which is higher than the liquor in the pan, to prevent the juice flowing down into the bearing of the lower pivots. The roller is supported in a brass step or bearing beneath the frame; and in some cases friction-rollers are applied beneath; the rollers are made of cast-iron, and hollow within, the external surfaces being truly turned.

The operation of this mill is extremely simple, the canes, as before observed, are made to pass twice under the pressure. This is frequently performed by hand, by two Negroes, situated one at each side of the mill; the first, who attends and feeds the Machine, takes the canes in a handful and applies their ends between the first pair of rollers, the motion of which draws them in, and they thus receive their first pressure; the other Negro, who stands behind the mill, and is termed the returner, bends the end of the canes as they come through, and holds them in contact with the surface of the central roller, so that it will carry them round by its motion and cause them to pass between the two other rollers. The second pair of rollers are adjusted so that their surfaces are rather nearer than the first pair, because as the canes are flattened and crushed by passing the first rollers they require a greater degree of pressure the second time. In the more complete mills they employ a dumb returner, instead of having a person behind the mill to return the canes; this is a circular piece of framework or kind of screen, which is firmly attached to the frame and made to encompass the back of the central roller. It receives the canes as they come through the first time, and holds them in contact with the middle roller until the ends return between the other pair, which contrivance not only saves labour but performs its work more completely than the most attentive returner can do. The canes which have passed through the mill are

squeezed perfectly dry, and are sometimes even reduced to powder. This refuse is called *cane trash*, and is used as fuel in the boiling-house.

Within a few years a considerable improvement has been made in sugar-mills by placing the rollers in a horizontal position, and arranging them in the form of a triangle, two rollers being below and one above, so that the upper roller, to which the power is applied, touches the other two, and, in fact, rests upon them; whereby the returner is rendered unnecessary because the two lower ones are so near together that the canes pass from one to the other.

(728.) Fig. 1, plate li., is a perspective view of a horizontal sugar-mill worked by steam. A A A is strong iron framing, firmly secured to the foundation of the mill; C D E are the rollers made fluted in the same manner as those already described as employed in the vertical mills; the two lower ones, D and E, have fixed bearings in the framework, and the upper one, to which motion is conveyed by the toothed wheels, F G H I, from the steam-engine, is made so as to admit of adjustment by wedges driven into the upper part of the framework; the lower rollers are placed very near each other, so that the canes are made to pass from one to the other; but as they move in opposite directions they cannot, of course, be suffered to come in contact. The advantages of placing the rollers horizontally seem to be considerable, as they admit of the mill being fed more regularly, which is done by spreading on a board or bench (seen at K in the figure) placed in a sloping direction, leading to the space between the upper part of the first lower roller, and the lower part of the upper roller. The canes, being pushed forward upon this board, enter between the two rollers and are carried forward to the other roller, and thus subjected to a second pressure, without the aid of a returner.

In vertical mills it is not at all unusual to find the rollers wear out in one part, which is generally about ten or twelve inches from the bottom, while the rest of the surface remains perfect; whereas the regular feeding of the horizontal mill causes a more equable working, and lessens the chance of accident from jerking or straining, and for the same reason the rind of the cane is less bruised, and its pith less broken in its passage between the cylinders than when the canes are carelessly crowded through them, intersecting and overlapping each other. In consequence, the cane-juice expressed by a horizontal mill is said to be much clearer and many shades lighter than that yielded by the vertical rollers.

When the canes have passed between the rollers they are received on another inclined board, which has sufficient slope to carry the cane trash from the rollers, and deliver it in a heap on the ground, whence it is taken from time to time and conveyed to the trash-house.

A full-sized horizontal mill should have rollers about five feet long and two feet diameter; if their diameter is smaller, a greater speed must, of course, be given in order to produce an equal effect, and the canes will also be more bruised than when larger cylinders are employed. A mill of these dimensions, propelled by a ten-horse power steam-engine, is capable of grinding with ease in twelve hours canes sufficient to make three hogsheads of sugar: with ten steers such a mill has been made to yield 840 gallons of juice in an hour and a quarter.

Manufac-
tures.Conversion
of juice into
sugar.*On the Manufacture of the Juice into Sugar.*

(729.) The juice which is expressed from the canes is an opaque fluid of a grey or dingy olive colour; it is composed of two parts, one solid and the other fluid, united more or less intimately according to circumstances. The operation of the manufacture of sugar consists in decomposing the expressed juice, so as to separate the feculencies or solid parts from the fluid, and by evaporating the water contained in the fluid syrup, a regular and crystalline union of the particles of sugar or essential salt takes place.

The feculencies contained in the cane-juice are of two kinds. The first, or coarser part, proceeds from the rind, and, together with a portion of mucilage, contains a quantity of green resinous matter; the other is an extremely fine powder, which comes from the pith, and its proportion is increased accordingly as the vessels of this substance are weaker: it also contains mucilage which is sometimes very intimately connected with it.

Heat decomposes the juice of the sugar-cane in common with all expressed juices, but its action, even when carried to the strongest degree of ebullition, rarely suffices to separate entirely the feculencies of the second sort; it often even favours their more intimate union with the fluid parts. In such cases it is necessary to have recourse to alkalis to obtain a perfect separation; this latter remedy is, however, invariably employed, notwithstanding there are circumstances under which heat alone will suffice to separate completely both kinds of feculencies.

The buildings required for the manufacture of the juice into sugar, and their particular relative situations, are, of course, dependent upon the size of the estate and its localities; it is, therefore, impossible to give any fixed rule for their dimensions, but as the situation of all the buildings is dependent on that of the mill, it is highly important to select the most eligible spot for its erection: there should be a fall from it to the boiling-house, so that the expressed juice may flow without assistance from one to the other. For the same reason a fall from the boiling-house to the still-house, and again from the latter, to allow the refuse from the stills to run off, will be very desirable, while the lower the situation of the mill, compatible with these circumstances, the better. The juice or liquor is conveyed from the receiver at the sugar-mill to the boiling-house by means of wooden gutters lined with lead, and is received there in one of the copper pans or caldrons termed clarifiers. In some cases the boiling-house is furnished with only one clarifier, but in general two or three are employed, and in some large concerns as many as four are provided, the dimensions of which are determined by the power of supplying them with liquor, as the means of quick boiling is in all cases indispensably necessary, or the cane-liquor will unavoidably become tainted before it can be exposed to the fire. Clarifiers are, in consequence, sometimes made sufficiently large to hold 1000 gallons each, but on estates which make on a medium 15 to 20 hogsheads a week (which is about an average quantity) three clarifiers, of 300 or 400 gallons each, are sufficient.

The clarifiers are made flat at bottom, and each is provided with a siphon or cock for drawing off the liquor. It is also necessary that they should be provided with a separate fire, and the chimney with which their furnaces communicate should have a damper for

regulating the draught, and diminishing or stopping at pleasure the combustion of the fuel.

Mechanical
Processes.

The stream from the receiver having filled the clarifier with fresh liquor, and the fire being lighted, the *temper*, which is commonly white lime in powder, is stirred into it. The quantity of alkali is sometimes determined by measure or weight, but is more generally regulated by the practical knowledge or discretion of the person in charge of the boiling, varying, of course, both with the quantity of the lime and of the cane-liquor. Some planters allow a pint of Bristol lime to every hundred gallons of liquor; but this proportion, Mr. Edwards is of opinion, is generally found too large. The lime is perceptible in the sugar, both to the smell and taste, and precipitates in copper pans a black insoluble calx, which scorches the bottoms of the vessels, and is not detached without difficulty. Mr. Edwards, in consequence, considers little more than half the quantity above mentioned to be a better medium proportion; and that Mr. Bousie's method of dissolving it in boiling water previous to mixing it with the cane-juice, is highly judicious, as it prevents the precipitation at the bottom of the vessel which very commonly attends the use of dry lime. An instance of the injurious effects of using too much lime is mentioned in Mr. Potter's Work on sugar, of an estate in the Island of St. Christopher, the produce of which had been uniformly inferior for upwards of fifty years, during which time it had been the practice to use 3 pounds of lime in the clarification of 300 gallons of cane-juice, which has, during the last few years, in consequence of reducing this proportion to 17 ounces of lime for the same quantity of liquor, yielded sugar improved in quality and value many shillings per cent.

After the lime is added to sugar-liquor the fire is allowed gradually to increase, during which time a scum is thrown up formed of the mucilage or gummy matter of the cane, with some of the oil, and such impurities or feculencies as the mucilage is capable of entangling. The juice must never be allowed to boil, and its temperature in this vessel should never exceed 210° of Fahrenheit. It is known to be sufficiently heated when the scum begins to rise into blisters, which break into white froth, and appear in general in about forty minutes; the fire is then damped, and, if circumstances will admit of the delay, the liquor is allowed to remain twenty or thirty minutes, or even longer, undisturbed in the clarifier, during which time there ensues a more complete rising and separation of the impurities; the liquor is then carefully drawn off, either by a siphon, which brings away a pure stream through the scum, or by means of a cock at the bottom: in either case the scum sinks down unbroken as the liquor flows out, its tenacity preventing any admixture. The advantage of clarifying the juice in this manner, instead of forcing an immediate ebullition, as was formerly practised, is very great: it saves a vast labour in the scumming, which would likewise be very imperfectly performed, as the whole body of the liquid would then circulate with great rapidity, and would carry down again the impurities which had risen to the surface. The merit of introducing into Jamaica the clarifiers at present in use, with siphons and dampers, was claimed by Mr. Samuel Sainthill, and an exclusive patent to secure his claim was granted to him in 1778 by an act of the Assembly.

The liquor is received from the clarifier into a gutter or channel, which conveys it to a vessel termed the evaporating boiler; it will now, if produced from good and

Manufactures.

untainted canes, appear almost if not perfectly transparent. The evaporating boilers, or evaporators, are generally four in number, the largest being of about the same dimensions as the clarifiers, and the smallest one, which is termed the *striking-teache*, about one-quarter of their contents.

The cane-liquor is here suffered to boil; the scum as it rises is continually taken off by large scummers, until the whole liquor grows finer and somewhat thicker. This labour is continued until, from the scumming and evaporation, the liquor is sufficiently reduced to be contained in the next or second copper, into which it is then removed by ladles. In this copper the same process of boiling and scumming are continued, and if the cane-liquor is not so clear as is wished lime-water is thrown into it; which addition is intended not merely to give more temper, but also to dilute the liquor, which sometimes thickens too fast to permit the feculencies to run together. When the liquor is again sufficiently reduced it is transferred to the third boiler, and so on to the last, or striking-teache, where the fire is more immediately applied; the scumming is continued throughout the process, and the coppers are sometimes kept constantly filled by lading the liquor from one to the other, as it is diminished by evaporation. The effect proposed by this is to prevent, or rather to mitigate the evil of burning the syrup, by keeping the whole surface of the copper in some measure protected from the overheating which would ensue in its upper portion, if left uncovered by the syrup. Some planters do not indeed extend this practice so far as the striking-teache, knowing by experience how necessary it is to remove the concentrated syrup as quickly as possible from the intense degree of heat to which it is subjected in this latter part of the boiling process.

The syrup remains in the striking-teache until, by evaporation, it is so far concentrated as to be capable of granulating in the cooler; and when the ebullition in this vessel is exceedingly violent, the syrup is kept from rising too high by beating it and breaking the bubbles with the ladle, or with a wooden spatula. The proper point of concentration having arrived, the fire is damped or drawn, and the sugar is laded into the cooler. The manner of judging of the required consistency is either by observing the granulations as the body cools on the back of the ladle, which is dipped into the teache for that purpose, or more commonly by taking a small portion from the ladle upon the thumb, then bringing the forefinger in contact with the same, and again separating them, noting the length to which a thread of syrup can be drawn before it breaks; if this extends to about half an inch long, it is judged that the sugar is fully boiled; but however much this plan may appear to be sanctioned by successful experience, it is evidently a rude and unscientific test. A better mode was suggested by Mr. Proculus Baker, in a Treatise published by him in the year 1775. He says, "Provide a small thin pane of clear crown-glass, set in a frame, on this drop one or two drops of the subject, and carry it out in the open air; observe the subject, and more particularly whether it grains freely, or whether a small edge of molasses separates at bottom." This method is used by Chemists to try evaporated solutions of all other salts; it may appear, therefore, somewhat strange it has not been adopted in the boiling-house; we believe, however, that this simple and efficacious plan, so long ago recommended, has not yet been gene-

rally adopted, and in some Colonies is, perhaps, unknown. Mechanical Processes.

The coolers, of which there are commonly six, are shallow wooden vessels about 11 inches deep, 7 feet in length, and from 5 to 6 feet wide. A cooler of this size holds a hogshead of sugar; and in these vessels the sugar as it cools runs into an irregular mass of semi-formed crystals, separating itself from the molasses. The cooling should be allowed to proceed slowly and gradually, which very much improves the grain of the sugar. From the cooler it is carried to the curing-house, where the molasses drains from it. It is of importance that the sugar should remain a sufficient length of time in the coolers before being put into hogsheads, time being absolutely necessary for the proper and perfect crystallization of the salts; and it is to be feared, Mr. Potter observes, that this operation of nature is often impeded, and much sugar is allowed to drain away in the shape of molasses, by too soon removing it into the hogsheads.

The curing-house is a large airy building provided with a capacious molasses cistern, the sides of which are sloped and lined with terras or boards; and over this cistern there is a frame of massy joint-work, without boarding, on which the empty hogsheads are ranged. In the bottom of these 8 or 10 holes are bored, through each of which the stalk of a plantain leaf is thrust 6 or 8 inches below the joints and long enough to stand upright above the top of the hogshead. Into these hogsheads the mass from the cooler is put, an operation which is termed *potting*, and the molasses drain through the spongy stalk and drop into the cistern, whence they are occasionally taken for distillation. This building should be sufficiently capacious to contain as many hogsheads of sugar thus placed as can be made on the estate during 3 or 4 weeks, in which time the sugar, although never entirely freed from molasses, will become tolerably dry and fit for shipment.

The above description of the process of manufacturing sugar will illustrate the general principle by which the reduction of the cane-juice and crystallization is effected; but in the order of the different operations, in the arrangement, and number of boilers and clarifiers, &c., considerable differences exist among the various manufacturers, some preferring the arrangement recommended by Dutrone, others the French method, but the greater number that described above.

(730.) Great improvements were certainly made by Dutrone in the Art of manufacturing sugar, and his method and arrangements of the building are still adhered to and preferred by some of the most scientific planters. In plate li., fig. 2, we have given the plan of the interior of a sugar-house as recommended by Dutrone. The vessels used for boiling are called collectively the laboratory, which generally consists of 3 or 4 boilers placed in a line; but whatever may be the disposition of the laboratory the order of the work is the same. The laboratory is placed in the sugar-house in such a manner that its two sides and the end formed by the concentrating pan should be isolated through the whole extent, in order that the attendance on them may be easy, and that the Negroes may be able to execute, with the greatest economy of time and means, every thing proper to be done for the perfection of the work. B B are the laboratories which are situated in the interior of the sugar-house; they contain each of them the four copper vessels *a b c d*, the capacities of which are from 500 to

Sugar-house described for Muscovado sugar.

Manufactures.

600 gallons. The first which receives the expressed juice is called the first clarifier, the next (*b*) the second clarifier, the third (*c*) the evaporator, the fourth (*d*) the concentrator. These vessels are placed very near to each other and have only an edge of 2 or 3 inches thickness between them. The masonry in which they are set forms the sides of the laboratory, the least thickness of which at the upper part is about 15 or 18 inches. The surface of the masonry is inclined 7 or 8 inches from the outer edge to the top of the boilers; there are between each, basins *e, e*, let into the masonry, where the scum which is taken off is put, in order that it may be carried back by channels *ff* to the first clarifier; between this vessel and the wall is a basin *g* which receives the first feculencies, whence they flow through a pipe *x* to a vessel (*h*) placed underneath to receive them.

It should be remarked that in the centre of the basins *e, e*, which are between the evaporator and the concentrator, there is an opening to a canal (*i*) which descends in the thickness of the masonry, and which is then continued horizontally to the bottom of a copper vessel (*k*) placed at the foot of the reservoirs for filtration and subsidence. A cooler (*n*) placed at the end of the concentrator forms also part of the laboratory. The filters *E E* ought to be large enough to contain all the expressed juice (diminished to the state of syrup, indicating 24° or 26° of the saccharometer) which the mill can furnish in 24 hours, and they should be made of masonry lined with lead and entirely covered with several sieves, the bottoms of which should be made with osier hurdles. There are fixed on these bottoms, for the purpose of filtration, first, a woollen, then a linen cloth, and lastly a reticulation of brass wire. Two leaden channels form a communication between the reservoirs and the laboratory; the one (*i*) conveys the evaporated syrup to the vessel (*k*) placed at the foot of each reservoir, whence it is poured upon the filters; the other, the opening of which is at the bottom of the reservoir *E*, carries back the syrup filtered and subsided to the concentrator.

When all is prepared for each operation, and the reservoirs for the expressed juice are filled with the proper quantity, it is made to flow into the first clarifier, and lime is added to it; and in order that the action of the lime may take place at the same time over all the juice, great care is taken to spread it by agitation for a minute or two with a ladle, and after having filled all the boilers with a charge thus tempered, heat is applied; the coppers, of course, receiving a degree of heat relatively to their proximity to the fire-place. The juice of the concentrator, therefore, is the first whose feculencies separate. These are removed by the scummer from each of the boilers as fast as they rise to the surface of the fluid and are poured into wooden buckets and carried to their place of destination (*h*.) Those of the first clarifier are poured into the basin, (*g*.) while the impurities of the second sort are poured into the little basins *e e*, and are carried back again to the first clarifier.

When the syrup of the concentrator indicates 22° or 24° of the saccharometer, the fire is damped, and the syrup is laded into the basin *e* which communicates with the vessel (*k*.) After having emptied the concentrator it is filled again with the entire charge of the evaporator, the heat is continued, and the contents of each copper pass successively from one to the other till they reach the evaporator, leaving the first clarifier

empty, and this is immediately supplied with a fresh accession of juice. In the mean time, as fast as the cane-liquor reaches the vessel (*k*.) it is poured upon the filters and falls into the reservoir freed from the solid matter which it contains. It is then in a fit state to be further concentrated by returning it the next day to the vessel *d*, whence it is conveyed to the coolers *H H*, in which the last operation, that of crystallization, takes place.

The sugar, the manufacture of which has been here described, is known as Muscovado or raw sugar, and is the material used by sugar-refiners in making white or loaf-sugar, which is also generally used for domestic purposes in England. There is also another description of sugar, which was formerly very much approved in Great Britain, known by the name of Lisbon sugar. It is still in very general use upon the Continent, and, from the additional process which it undergoes, is called in the West Indies Clayed sugar.

(731.) The process employed in the manufacture of this sugar does not differ from that above described, until it arrives at the coolers, when, instead of being removed to the hogsheads, a quantity is put into conical pots or pans, called by the French *formes*, which are placed with their points downwards, and have a hole at the bottom through which the molasses drain, but which is at first closed with a plug. When the sugar in these pots is cool and becomes a fixed body, which is generally in about twelve hours from the first putting in of the hot sugar, and may be known by the middle of the top falling in, the plug at the bottom is taken out and the pot placed over a large jar intended to receive the syrup or molasses which drain from it. In this state it is left until the molasses cease to drop, which will be generally in from 12 to 24 hours, when a stratum of clay is spread on the sugar and moistened with water, which, oozing imperceptibly through the pores of the clay, unites with and dilutes the molasses, consequently more of them come away than from sugar cured in the hogsheads, and the sugar, of course, becomes so much the whiter and purer. The pots remain for 20 days in this situation, after which the sugar is taken out and dried in the sun for some hours, and then taken to a large stove room, where it is kept in a pretty strong heat for three weeks. The stoves which adjoin the curing-house are built of masonry nearly 20 feet square, having the interior divided into different stages upon which the loaves are placed, and when sufficiently dried they are removed from the stoves and pulverized in wooden trays, from 12 to 15 feet long, and from 3 to 4 feet wide. The sugar thus pulverized is put into hogsheads and pressed down, that the casks may contain as much as possible, and is exported under the name of Clayed sugar.

This process, according to Sloane, was first discovered in Brazil accidentally by a hen with dirty feet going over a pot of sugar, which was found under her tread to be whiter than elsewhere. This method is almost universally adopted by the French planters, although generally disapproved by the English, who state, that the water, which dilutes and carries away the molasses, dissolves and carries away with it so much of the sugar, that the difference in quality does not pay for the difference in quantity. The loss in weight by claying is about one-third, so that a pot of 60 pounds is reduced to 40 pounds; but if the molasses which are drawn off in this practice be reboiled, they will give nearly 40 per cent. of sugar, so that the real loss is little more than one-sixth: but

Mechanical Processes.

Manufactures.

the distilling in that case will suffer for want of molasses, and, on the whole, Mr. Edwards considers that the method adopted by the English planters in shipping Muscovado sugar and distilling the molasses, is more generally profitable than the system of claying.

It is unnecessary to enter into a description of the variations from the above processes which are recommended by Dutrone and others, and practised by some planters; it will be sufficient to say, that the general principle is the same throughout, the variations above referred to consisting simply in the number or arrangement of the boilers or clarifiers.

Patents for the manufacture of sugar.

(732.) Several patents have been taken out within a few years for improvements in the manufacture of sugar, of which the following are most worthy of notice. In 1823, Mr. James Smith took out a patent for a method of heating boilers by high pressure steam, which has the advantage of not burning any material submitted to its action. It is proposed to apply this principle to the boiling of cane-liquor by means of double-bottomed vessels, the space between the two forming the steam boiler, but is not to subject the clarifiers to the action of steam, but simply to apply to them a more gentle degree of heat by means of the warm air of the flue previous to its passing into the chimney. We believe, however, this invention has not been introduced to any extent into the West Indies, which is probably owing to the danger and liability to derangement which attends the use of high-pressure steam.

A few years after another patent was taken for the use of high-pressure steam in heating boilers by Mr. William Fawcett of Liverpool. By his arrangement all the sugar pans were placed in a large boiler which was also proposed to supply the steam-engine.

This arrangement is said to have been successfully tried in Jamaica; but it appears to be subject to the same objections as those which have been urged against the employment of high-pressure steam under Smith's patent, namely, its danger from the degree of elasticity at which the steam must be used, and the great liability to derangement of the apparatus in a Country where engineers are not very numerous, and where few, if any, among them can lay claim to the skilfulness and ingenuity of the inventor. The unavoidably high cost of such an apparatus must also be a considerable drawback to its adoption.

In the year 1828 Mr. J. T. Beale and Mr. G. R. Potter obtained a patent for the invention of a new mode of communicating heat which can be advantageously applied to the manufacture of sugar from the same juice. This invention affords the means of regulating and controlling the degrees of heat with great precision, by transmitting caloric to the syrup by the intervention of certain fluid substances, which, unless they are purposely subjected to pressure in close vessels, can never be made to indicate beyond certain degrees of temperature, so that the degree of heat adapted to any particular operation being known, a fluid medium may be chosen and applied which will communicate that degree and no more.

This method seems to embrace all the advantages that can result from high-pressure steam, and at the same time the danger, complication, and liability to derangement is greatly avoided. The maximum degree of heat being by this arrangement altogether independent on accident or want of skill in the attendant, no injury from burning can possibly take place unless

through the choice of an improper fluid medium, which need never occur, as substances may be chosen capable of communicating any given temperature between the boiling point of water, and even lower, and the melting point of lead.

Mechanical Processes.

Mr. Godfrey William Kneller has lately patented an invention for improvements in evaporating fluids, which has been successfully employed in an extensive sugar-refinery in London, and seems to be applicable to the Colonies. The apparatus consists of a set of pipes which are inserted in the liquor to be concentrated, and which reach nearly to the bottom of the pan. Through these pipes the air is forced by means of bellows or any other blowing contrivance, and this air, escaping through the fluid, is said to carry off the watery vapour with much greater rapidity than where the strongest heat is applied, under the most favourable circumstances, without this operation.

Mr. Kneller's process seems to offer the means of concentrating syrup at a temperature equally low with the celebrated vacuum apparatus invented by Mr. Howard, and with a degree of simplicity which renders it attainable by the sugar-planter.

Sugar-refining

(733.) Sugar-refining is the Art of extracting the molasses and other extraneous matter from the sugar, and thereby giving to it a superior degree of whiteness and solidity. The Art of refining sugar was first introduced into Europe by the Venetians, and was practised in Venice some time before it was adopted in any other European Country. The foul and black sugar brought from Egypt, at the end of the XIIIth Century, was the first material upon which the Art of the refiner was exercised, which the Venetians in their commencing attempts converted into sugar-candy, similar to that which came from India; but they soon sought to obtain the sugar by a quicker and more profitable process, and for this end they invented the form of a cone or loaf, the use of which obtained universally and has continued to the present day.

Sugar-refining.

The Art of refining passed afterwards into every part of Europe in which sugar was an article of commerce and consumption; and, since America has been so fertile in the production of this commodity, refineries have consequently increased and extended all over Europe. The process of sugar-refining may be divided into two distinct operations: first, that of separating the earthy and solid parts; and, secondly, of expelling the molasses and fluid parts. The former process is effected in the common operation by bullock's blood and lime-water, and the latter by claying. Within a few years, however, improvements and alterations so marked have been made by Mr. Howard and others, that this method is in a great measure supplanted by the more modern improvements. We have, therefore, not entered at very great length into the description of it, and beg to refer the readers who are desirous of more particular information on the point to Mr. Potter's Work, in which it is described at great length.

(734.) The sugar is first boiled in pans with about six quarts of bullock's blood and a small quantity of lime-water, and the scum and impurities produced by the successive additions of bullock's blood is continually removed, till the sugar casts up only a clean milky froth which indicates the removal of impurities; and in order to heighten

Old process of refining.

Manufac-
tures.

the whiteness a little of the finest indigo is added. In this operation the heat of the fire is applied directly to the pan containing the sugar.

The next process is that of evaporating the pure saccharine solution. This is effected by a moderate fire, and the boiling is continued till the sugar has the proper degree of viscosity or ropiness, which is easily ascertained by what is called the proof-stick.

When the evaporation is completed, the hot sugar-liquor is removed out of the pans into coolers, and it is here gently stirred to prevent the formation of a crust; it is then granulated by an oar, the violent motion of which, continued for several minutes, destroys the viscosity of the sugar, and completes the granulation, the beauty of the sugar depending on the perfection of this process.

The next step is to fill the moulds, which are earthen vessels like inverted cones, the apex being placed undermost; the clarified concentrated sugar is then poured in by three successive pourings. In order to prevent the adhesion to the moulds and to lay the grain of the mass evenly and regularly throughout, the sugar is scraped from the sides of the cone by an instrument termed a bottoming trowel, and the fluid is allowed to rest a few minutes till it has got some firmness. The moulds are then stirred round three or four times and the first process is finished.

The moulds are placed above pots, and the stopper or rag at the bottom, or apex of the moulds, having been previously drawn out and a punch made with an awl, there will exude from this aperture a quantity of syrup or molasses, which is removed at the end of about twenty-four hours, and the pot replaced under the apexes of the moulds. A small ladle-full of wet clay is then poured on the face or base of each loaf or cone of sugar, which, after drying into a cake in five or six days, is removed and laid by for future use. On the day following the loaves are clayed a second time, and the cake when dry is removed like the first. The cakes are now drawn out of each mould and the irregularities and impurities brushed off, and when they have acquired sufficient hardness of surface, they are dried in a stove for five, six, or seven days to render them fit for sale.

The above is the process for single loaves or sugar once refined; but the double loaves, or those double refined, are made by a process in which the clarification is effected by the whites of about 200 eggs to each pan, and with fresh water instead of lime-water.

In the common method of refining sugar from 20 to 35 per cent. of molasses are found in the pots, and it is supposed that about two-thirds of this are produced by the intensity of the heat employed for concentrating the syrup. Various attempts have been made to remedy this evil, and in 1812 and 1813 the celebrated patents of the Honourable Edward Charles Howard were granted, although it was not until some time after this period that, through the unwearied exertions of Mr. Hodgson, these improvements were introduced.

Howard's
patent.

(735.) Mr. Howard's first patent related more particularly to the method of preparing and fining the sugar: the second to the manner of applying and regulating the heat. The sugar refined by this process is submitted to an operation preparatory to boiling, that is, raw sugar is mixed with such a quantity of water as to form a magma of the consistency of well-worked mortar: after being left at rest for the space of an hour or two, it is heated to a temperature of 190° to 200° Fahrenheit, (the improved manner of

applying heat will be described hereafter,) a thinner Mechanical
magma of sugar is added, and the whole is then put into Processes.
moulds, and when it becomes cold these are unstopped and the molasses suffered to drain from them. When the draining is completed, the upper portion of the mass of sugar is pared down to a uniform surface: the sugar so pared off is mixed with cold water till it acquires such a consistency as will not readily allow of its closing behind the stirrer, in which condition it is replaced on the firm even surface before prepared. As soon as the magma becomes moderately dry, a saturated solution of fine sugar in cold water is poured upon it about half an inch deep, or the magma may be taken off, rewetted, and replaced on this surface, and one or other of these operations must be repeated as often as the nature of the sugar may require. When this proves open-grained the finer the sugar of which the magma is made is ground the better, because the moisture is thereby prevented from descending too fast or unequally into the loaf.

The loaves are frequently examined, and the proper period for terminating the operation is ascertained by observing the degree of freedom with which the moisture is admitted, and by the colour of the molasses which drips from them. The temperature of the place in which this process is conducted should be about 60°, and raised to 80° or 90° after the surface of the loaf becomes dry for the last time. It is necessary to perforate the surface when it becomes so solid or hardened over as to prevent the access or escape of air into or out of the sugar, as otherwise the free percolation of the molasses would be impeded.

This primary operation being completed, the neat sugar is divided in the usual manner from that which retains the molasses, the former is then refined by pouring upon it 6 pounds of boiling water to every 5 pounds of sugar, deducting about 6 per cent. for the moisture previously contained in it. The sugar is dissolved by stirring, and the impurities are allowed to subside; the solution is then drawn off from the impurities, and, to complete its clarification, finings are now added, which are prepared by slacking well-burned lime with boiling water so as to obtain a cream of lime; to this is added an equal bulk of water, and the mixture is boiled for some minutes until the lime assumes the appearance of fine curd; the extraneous matter is then washed away, and the lime and liquor are run through a fine sieve.

The next part of the process is to dissolve about 2½ pounds of alum, for every hundred-weight of solid sugar that is to be refined, in about 16 times its weight of water, and to add to such solution about 70 or 80 grains of whitening for each pound of alum; and, after stirring up the mixture till the effervescence ceases, the suspended substances are allowed to subside and the solution is drawn off from the precipitated matter, and after this, are put into it the prepared lime curds shaken up with the water, the whole being agitated during the effusion. The quantity of curds must be such, that turmeric paper shall barely change its colour by being immersed in the mixture, and shall recover its yellow colour when dry. The finings thus duly prepared are suffered to settle to the bottom of the containing vessel, and, after draining off the supernatant liquor, the finings are placed upon blankets supported in the manner of a filter, and the moisture is drained off until the mass begins to contract and crack on the surface; and in this state the finings are fit for the clarification of the sugar last drawn off as

Manufac-
tures.

above described, such a quantity of that solution being added by degrees and with stirring, as will bring them to a uniform creaming state. This mixture is then poured into the whole quantity of the solution of sugar prepared for clarification, and agitated sufficiently to diffuse the finings equally.

The refined or clarified sugar is suffered to remain either during the night or about six hours, and the bright liquor drawn off from the finings by the usual methods. An evaporation is commenced and carried on at the temperature of about 200° , which is best effected by the heat of steam or water under the common pressure of the atmosphere, until the hot liquor shall have acquired a specific gravity of about 1.37; and in this state it is transferred to any convenient vessel and stirred frequently until it assumes the proper granular consistence to fill the moulds. The stoppers are taken out of the moulds as soon as the liquor is cold, and the syrup is allowed to run from it in the usual manner. During this operation, when the syrup has left the upper surface of the lump, it is pared down as before described, and if the sugar appear sufficiently fine for market, it is taken out of the mould and dried in the ordinary way, but, if it is not, the sugar before pared off the surface is mixed up to a magma with water as in the primary operation.

Mr. Howard, in the specification of his second patent, dated on the 20th November, 1813, recommends that the refining of sugar shall be effected by placing it, mixed with a proper proportion of finings, in a vessel having a perforated bottom, through small holes of which steam is allowed to enter, until the sugar is fully dissolved and heated to the temperature of 200° Fahrenheit's scale. He then proceeds, either by filtration or subsidence, to remove the impurities of the sugar: if by filtration, the solution is made to pass through Russia duck cloth; and in order to assist the operation, the heat should be kept as nearly as possible to the degree above mentioned: if the impurities are separated by subsidence, the solution must be further diluted until its specific gravity is not more than one-fifth that of water.

The most important part of Mr. Howard's invention consists in his availing himself of the fact, that fluids will boil at much lower temperatures when relieved from the pressure of the atmosphere, than when under the ordinary atmospheric pressure. He places the syrup in a close vessel, so formed as to allow the access of steam to its exterior surface for the purpose of heating its contents, and employs an air-pump with a condenser for steam by injection as used in steam-engines, so as to make and keep such a vacuum in the concentrating vessel as will not support more than one inch of mercury.

As the employment of vessels thus constructed, of course, renders impracticable the usual method of examining the progress of concentrating in the syrup, Mr. Howard furnished a scale of pressures by the mercurial gauge, and of corresponding temperatures whereby to regulate the process; and he likewise described an instrument, by means of which a sample of the liquor may at any time be taken without admitting air into the pan. This instrument, or proof-stick, is a tube inserted in an inclined position through the side of the pan, fitting air-tight at the juncture: the outer end of the tube is open, the inner end closed; but an aperture is made low enough to be immersed in the saccharine solution; concentric with this tube is inserted

another short tube, which is capable of being moved by rotation one-half turn, and has an aperture corresponding to that in the fixed tube. A plug is then constructed so as to lay hold of this inner tube, and to turn it, that its aperture may be made to coincide, or otherwise, with the aperture in the fixed tube. This plug has a cell or chamber, so situated, that when inserted for the purpose of examining the solution, it will be filled through the apertures in the tubes, when, the inner tube being turned round, the apertures will no longer coincide, and the plug, with the syrup it contains, may be withdrawn, without allowing the external air to communicate with the contents of the vacuum-pan.

When the sugar is sufficiently concentrated, Mr. Howard directs it to be withdrawn into a granulating vessel, whose office is similar to that performed by the usual cooler; this vessel, by means of steam applied to its external surface, is heated to a temperature of 150° to 180° Fahrenheit, and the usual stirring is given to effect granulation, raising the heat to 200° before filling the moulds. By this elegant method of concentrating saccharine solutions, all danger of over-heating is clearly avoided, and, as a consequence, the sugar presents a boldness and brilliancy of crystals, which had never been attained by any previously known method.

(736.) An important improvement in the manner of expelling molasses or syrup from sugar has lately been introduced by Mr. John Hague, of Cable Street, Well-close Square, who took a patent for his invention in 1816, and subsequently for the Colonies in 1828. The process is carried on by placing the sugar in a vessel or trough, having a perforated false bottom. Connected with the space between the two bottoms is the suction-pipe of an air-pump, by which a partial vacuum is formed beneath the sugar; the air in consequence rushes through, and carries with it through the perforations in the false bottoms all the molasses, leaving only the crystallized sugar in such a state that it may be immediately shipped without any liability to loss by drainage on board the vessel, or to any decomposition of the crystals through the injurious action of the impurities from which it has been thus freed. All the molasses and impurities which have been so separated are preserved for the still-house.

Sugar thus treated commands a price in the market greater than could be obtained for the same sugar in its original state by about 15s. per hundred-weight. This, however, is not all gain, as the molasses usually sold in the sugar would serve to increase by about 25 per cent. the quantity brought to market. It is stated that in the cleansing operation the crystals of sugar are washed and lessened; this, however, must be rather a fancied objection than a real one, as it is the beauty of the colour which the grower regards of most value, and the goodness of sugar for refining is by no means impaired by any artificial lessening of the grain. In newly-settled estates, and where from any cause the sugar proves dark in colour and reluctant to part with the molasses, Mr. Hague's apparatus cannot fail of proving decidedly advantageous. We understand that on a plantation where this invention is adopted, a steam-engine of twelve-horse power is sufficient during an ordinary day's working to furnish cane-juice for six hogsheads of sugar, and to expel the molasses from four hogsheads. We are also informed that Mr. Hague's patent is adopted by some sugar-bakers in France as

Mechanical
Processes.

Manufac-
tures.

the first step in refining raw sugar; but in such cases the molasses are not expelled so expeditiously or effectually as when the sugar is newly made. The adoption of this invention is now becoming very general throughout the Colonies, and it is likely entirely to supersede the more tedious and less effectual method of claying.

Other methods have been invented for expelling the molasses without the aid of heat. Mr. John Taylor obtained a patent for a mode of separating the molasses, and other soluble impurities, by mechanical pressure. The raw sugar must first be brought to a moist state, either with cold water or lime-water; but no exact rule can be laid down for the degree of moisture to be given, as it depends much on the quality of the sugar, but in general the proportion of water may be from one-eighth to one-tenth the weight of the sugar. They must be well mixed in any suitable vessel, and the whole then subjected to a pressure, carried to such a degree as to express all the fluid part therefrom; this will be found to contain the molasses and soluble impurities, and if the pressure be sufficient, the sugar will be rendered dry and much improved in colour and appearance.

The process has been tried with success in some establishments; the more general adoption, however, of Mr. Hague's invention will, of course, remove the necessity for this operation in Europe; and it would appear that the impurities can be more readily separated from the sugar when recently made, and before they have acted injuriously upon the crystals. It seems desirable on every account that the separation should be effected previously to its exportation.

We have now mentioned the most important improvements in that part of the refining process, which consists in extracting the soluble impurities contained in the sugar. In the remaining process, or that by which the earthy and other insoluble parts are separated from the pure saccharine matter, the inventions have been very numerous. We mention the following, which have been most adopted.

Two years after Mr. Howard's invention, *i. e.* in 1815, a patent was granted to Messrs Martineau for a new method of clarifying vegetable substances. The articles employed by the patentees for clarifying sugar were, first, animal charcoal; second, bituminous earths; third, certain argillaceous earths; and, fourth, the vegetable charcoal usually called lamp-black. The first-mentioned articles are, however, preferred in the process of refining and clarifying sugar, as they render it much whiter than when clarified by the common method; they are applied to clarifying in the following manner. The sugar-pans are filled with sugar and water, or lime-water, as in the common method; to this the above-mentioned substances are added, in proportions varying with the quality of the sugar to be refined—from two to five pounds of charcoal for every hundred-weight of sugar. Rather more than the usual proportion of eggs, blood, or other albuminous matter, is added, in order the better to coagulate with the dirt contained in the sugar; the liquor is then well agitated in the pans that the charcoal may produce a greater effect in blanching it; and after the coagulated albumen has completely risen in the form of scum, by the application of heat in the usual

way, it is either removed, as in the common process, or the whole of the liquid sugar is poured upon the filters at once. This method is found to whiten and purify the sugar, but it is said that more than the usual waste attends its employment. It is adopted in several refineries.

In 1817 a patent was granted to Mr. Daniel Wilson for certain improvements in boiling sugar. The object of this invention was to preserve the sugar from being charred through the exposure of the pans to the naked fire, from which they were wholly withdrawn, and their contents heated by an injection of boiling oil through tubes coiled in them. The oil which was heated in a separate boiler, and impelled through the tubes by the action of a forcing pump, returned again to the boiler after communicating heat to the sugar, in order to be re-heated and injected as before, thus establishing a constant circulation through the tubes.

This plan was pursued in one very considerable refinery some years back, which was burned down, and was the occasion of litigation with the Insurance Offices. Since that event we believe that none have been constructed on this principle.

In 1828, Mr. John Davis patented a method of boiling sugar at low temperatures by means of a Torricellian vacuum, which he obtained by connecting his sugar-pans with the upper part of a condenser, situated upwards of thirty-three feet above the level of the place at which the water from it was discharged; and as the pressure of the atmosphere does not sustain a column of water exceeding that elevation, the apparatus being first filled with water, which was permitted to escape at the lower extremity, a perfect vacuum would be obtained in the upper part of the apparatus, provided it were made completely air-tight.

In the same year, Mr. Cleland took a patent for improvements in sugar-refining, which wholly apply to the evaporation and concentration of the syrup. The principle of the invention consists in continually exposing a thin film of the liquid to the joint actions of heat and air. The apparatus consists of a convoluted worm of great length, into which steam is introduced; this is made to revolve horizontally on its axis, partly immersed in the liquid under evaporation, which is thereby constantly taken up by it in the thinnest possible stratum, and, being in contact with the hot surface of the metal, the aqueous portion of the matter is quickly formed into steam and carried off by the surrounding atmosphere.

Mr. Cleland's invention was used for some time in an extensive sugar-house in London, and was found to possess some advantages; but its use has been lately abandoned for the apparatus of Mr. Kneller, which has been before described under article Manufacture of Sugar, to which it is equally well adapted.

We shall conclude the present section by Tables of the quantities of sugar imported and exported, referring the reader who wishes for further information to Mr. Potter's valuable Treatise on the *Culture of the Sugar-cane*, to which we have been much indebted for several of the preceding particulars.

Mechanical
Processes.

(737.) Account of the Quantity of Sugar imported into and exported from the United Kingdom, the Quantities cleared for Consumption, the Rate of Duty, and the gross Amount of Revenue thereon; also the Amount of Drawbacks and Bounties allowed upon Quantities re-exported, the Net Produce of the Duty, and the Average Prices in each Year, commencing on the 5th January, from 1820 to 1831, both inclusive.

*Works relating to Bleaching, Dyeing, Calico-printing, and Tanning.**Bleaching Works.*

Bleaching. (739.) *Bleaching* was formerly quite a distinct operation from dyeing, and conducted by different parties, and in distinct Works, and is still so generally when the cloth is to be left white for the market, but when the bleaching process is only preparatory to that of dyeing or printing, it is very commonly carried on in the same premises, and is, in fact, considered only as another branch of the dyer's art. We shall therefore, while we keep the process distinct from that of dyeing or printing, so far combine the three subjects as to give them in continuation, disregarding the alphabetical order of those articles which would interpose between them.

In consequence of the great advancement of the Science of Chemistry, most of the Arts depending upon it have undergone great changes, and all have been more or less improved; but there is not one, perhaps, in which the improvement has been so great, and the time of the whole operation so much expedited, as that of bleaching. The same materials, which formerly were submitted to a tedious and troublesome process for five or six months, can now be rendered as perfectly white and free from dirt in the space of a less number of days, by the use of oxy-muriatic acid or chlorine; and, in consequence of this, the old method of bleaching is now almost entirely superseded by the improved process. We shall therefore make the description of it as brief as possible, in order that greater length may be given to illustrate the modern practice.

Manufac-
tures.*Sketch of the Old System of Bleaching.*Old system
of bleach-
ing.

(740.) The first operation in the old system, as in the new, is to remove a substance termed sowens, which is a paste made of flour and water, used during the weaving for the purpose of closing down the fibres of the threads, and thus allowing them to pass more freely through the reed and harness; this consisted in steeping the goods in a vessel of lukewarm water, till a gentle fermentation took place, which usually required about twenty-four hours. The cloth was then taken out and well washed in a current, which removed a considerable quantity of the filth without the use of alkaline leys.

Boiling.

Boiling.—The goods were then boiled in a vessel containing a solution of potash, and furnished with a winch and rollers, by which the cloth could be moved about in the liquor, and by that means thoroughly impregnated with it. This was continued as long as the liquor appeared to abstract any colouring matter from the cloth, which was then taken out and well washed in water. The use of this process depends upon the properties which alkaline salts possess of uniting with the oily and resinous matters which are either attached to, or are a constituent part of, the vegetable fibres.

Bucking.

Bucking.—The next operation is termed bucking, and is similar in principle to the last, although a more powerful application of it. The goods are placed in a vessel termed the bucking-tub, and a powerful solution of the alkaline ley is poured upon them from a vessel where a quantity is kept constantly boiling. When the goods are thoroughly impregnated with the boiling ley, it is allowed to pass off into an iron vessel, whence it is pumped back again to the boiler, and then returned hot again upon the cloth, which process is continued for some time. The cloth is then taken out, well washed from impurities, and laid upon the ground to be whitened by exposure to the atmosphere.

Souring

Souring.—In order to dissolve and remove any metallic or earthy matter inherent in the cloth, or which may have been derived from the impurity of the alkaline solutions, an operation termed *souring* is employed: the goods are immersed for about the space of twelve hours in a mixture of sulphuric acid and water well incorporated, the proper strength of which should be about the acidity of lemon juice, and was usually determined by the taste. The goods may be put into this acid either in a wet or dry state; but the best plan is to immerse them in the evening in the acid liquor cold, to let them remain covered with it all night, then in the morning to make a fire and bring the liquor to a blood heat, in which state the goods should have a few turns, in order that every part of them may be equally exposed to the fluid. The goods are then wrapped round the winch to strain them a little, to prevent an unnecessary waste of acid, and afterwards carried to a wash-wheel or river, to be washed till there is no acid perceptible to the tongue remaining in the cloth. It is a remarkable circumstance that cloth may remain immersed a considerable time in strong acid liquor without rotting, but that, if exposed to the air or the heat of a stove, if a very small portion of the acid remains in the cloth, it becomes so concentrated by heat as to damage the material immediately, too much attention cannot, therefore, be paid to this point.

The operation of bucking was repeated for some cloths a great many times, each time requiring, with the subsequent operation of leying and watering in the

bleach field, the period of a week. The first two buckings were with very strong ley, which it was necessary to diminish in strength to prevent injury to the cloth.

Mechanical
Processes.

These operations could be carried on only during the Summer months, and during four months in the year bleaching by the old system was entirely suspended, and the capital of the manufacturers, or proprietors of the goods, locked up and useless; the immense time which the goods were under operation was also the means of a great consumption of capital. Cotton goods, which required from four to six applications of alkaline leys, consumed as many weeks in bleaching, while linens, which could not be bleached in less than from twelve to twenty applications, could scarcely be brought into a marketable state in less than six months.

Discovery of the new Principle.

(741.) Such was the state of this Art when Scheele first discovered the gas, for some time designated by the term oxymuriatic gas, but which has since been more properly named chlorine. It is generally considered that Berthollet had the honour of first suggesting the application of this material to the purposes of bleaching, and that he did, in fact, make the application in a small way in 1786. (*Ann. de Chim.* vol. ii. p. 160.) Others, however, seem to dispute this point, stating that the idea of its application belonged also to Scheele; that the latter Philosopher wrote to Kirwan, informing him of his discovery, and its application; that Kirwan mentioned the subject to Mr. Taylor, then Secretary to the Society of Arts, altogether independently of Berthollet; and that a whole piece of calico, in the state received from the loom, was, in the Spring of 1788, actually bleached, printed in permanent colours, and produced in the market at Manchester for sale, having undergone all these processes in less than forty-eight hours. This is very probable, but it does not appear to prove any thing with respect to the first suggestion of the application of the oxymuriatic acid to the bleaching process, nor is it, we conceive, of great consequence. There is no doubt that Scheele discovered the gas and its properties, and there is as little doubt that Berthollet contributed greatly to the progress which was afterwards made of the discovery to bleaching in the large way; but both seem to have been erroneous as to the theory of its action.

Scheele's
discovery.

Scheele explained the bleaching power of the oxymuriatic gas, by supposing that it destroyed colour by combining with the phlogiston, while Berthollet considered it as acting by supplying oxygen, whereas it was afterwards found that, although this new gas had received the denomination of oxymuriatic gas, it could not be shown to contain oxygen, and it could not contain muriatic acid, consequently, explanations resting on these false hypotheses were necessarily defective.

Amongst those who had the advantage of witnessing Berthollet's experiments was the celebrated Watt, who himself afterwards made some experiments, and succeeded in whitening five hundred pieces of cloth. He did not, however, pursue the subject any further, probably in consequence of his other important occupations.

About the same time a gentleman, named Cooper, formed an establishment for the purpose of applying Berthollet's discovery, and Dr. Henry of Manchester, not only engaged in a similar undertaking, but gave to

Manufac-
tures.

some of the principal bleachers the first instructions which they received respecting the new process. Dr. Henry recommended two methods of applying this principle. One consisted in immersing the goods in a watery solution of the gas, or in an alkaline ley impregnated with it, the other in exposing the goods, previously moistened with water, to the gas itself. He afterwards made an improvement by substituting lime for alkali, as a means of condensing the new gas. An air-tight chamber was prepared, on the floor of which rested a stratum of lime and water mixed together to the consistency of cream; through this chamber the goods were passed by means of a winch, and the chamber being filled with gas, the goods were alternately exposed to the lime liquor and to the acid vapour. By this means an oxymuriate, or, as we should now say, a chlorate of lime, was formed upon the cloth, which, after a sufficient continuance of the operation, was taken out and exposed to the usual process of washing, &c.

A very essential improvement in the application of lime was afterwards made by Mr. Tennant of Darnley near Glasgow, which was secured to him by a patent in 1798. It consisted of a combination of the chlorine with lime in a separate vessel, containing lime suspended in water by mechanical agitation. The redundant lime was allowed to subside, and the clear liquor, a solution of chlorate of lime, obtained, which was applied to the purposes of bleaching. This patent was afterwards set aside by the decision of a Court of Law.

Modern System of Bleaching.

(742.) The great distinction between the old and modern system of bleaching consists principally in the substitution of immersion in chlorine, for the effect formerly produced in the bleaching ground by the atmospheric air; the primary processes being the same in both, in the modern processes may therefore be thus classed, viz. steeping, bucking, boiling, immersion, souring, and washing.

On steep-
ing.

Steeping.—After the linens are properly sorted, they are washed for some hours, in order to free them from any loose matter which may be attached to them: they are then put into a large circular vat made of fir deal boards, technically termed a *kieve*, one above the other, without being too much compressed. After the goods are disposed in the kieve, it is filled with alkaline ley at a blood-heat, generally some which has been employed in bucking or boiling former goods. A piece of wood in the form of a cross is then fixed above the cloths in order to keep them below the liquid. In a few hours an internal motion is observable and an increase of temperature takes place, the liquid swells, bubbles of air rise to the surface, and a thick scum is thrown up. This fermentation continues from twelve to eighteen hours, according to the state of the weather, and as soon as it is observed to have ceased, the goods must be instantly withdrawn from the kieve and again washed, in order to be cleared from the loose filth. If they are kept too long in the steep, they are liable to considerable damage, as, after the acetous fermentation ceases, a putrid fermentation commences, and the coloured matter, instead of being loosened from the goods, is attached to them, and at the same time a dissolution of the vegetable fibre takes place, and, were they to remain too long in this state, they would be totally destroyed.

Boiling and bucking.—Boiling is now very commonly omitted, and if not, only used when the goods are nearly white; the process which follows the steeping being that of bucking, in which considerable improvements have been made. In the old method, the goods having been placed in a wooden vat, the hot alkaline ley from a boiler was admitted upon them, and, after having remained some time, it was let off by a cock at the bottom, to be returned to the boiler to be fresh heated and again admitted hot upon the goods in the kieve. It is found, however, that the admission of the liquor when hot upon the goods has a tendency to fix the colour more strongly upon them, in place of extracting it; for this reason the latter are placed in the cold liquor, which is gradually heated, and by that means the colouring matter is more effectually removed than can be accomplished by the old method. When the alkaline ley is saturated with the colouring matter, it is run off, and, instead of the former plan of carrying the goods instantly to the dash-wheel while hot, whereby a certain portion of the colour is fixed into them, the most scientific bleachers, after the ley is let off, run warm water upon the cloth, which combines with and carries off part of the remaining impurities; a stream of water is then allowed to run upon the cloth in the kieve until it comes off almost transparent. The linens may now be taken to the wash-wheel to be further cleaned without any danger of setting the particles of colour.

Immersion.—Thus far the processes described do not materially differ from the old system; we now arrive at the point where the great change takes place. The goods, instead of being laid in the grass fields for several days, are immersed in water impregnated with chlorine, chlorate of potash, or chlorate of lime, for the period of six or nine hours, after which they are washed and again submitted to the bucking process; they are afterwards again immersed in the chlorine solution, and these last operations are repeated alternately for several times, the number depending upon the nature of the materials to be bleached.

Souring.—The goods after being properly washed have now to be soured, which operation differs so little from that already described as employed in the old method, that little requires to be said on this point. The sour is prepared in a large fir tub lined with lead; as much sulphuric acid is added to the water as will give it the acidity of strong vinegar. The acid and water must be well mixed together before immersing the linens, which are generally steeped in it for twelve hours, and then dried and washed in pure water. Linen yarns and cloth are passed three or four times through the acidulous water, making it progressively weaker each time, but it is sufficient for cotton goods to be passed once. Great pains must be taken to wash the cloths perfectly before and after immersion in the acidulous water, otherwise a fine white can never be attained. It is no less important to prevent the yarns or cloth impregnated with acidulous water from remaining long exposed to the air, for, as the water evaporates, the acid becomes concentrated and the fibre is destroyed.

The souring process very commonly completes the bleaching. Some of our most eminent bleachers, however, commit the goods to the sour much earlier, which, they say, considerably hastens the removal of the colouring matter.

It is very essential that the goods should be now well

Souring.

Manufac-
tures.

soaped to correct the rigidity which is given to the fibres by the ley. Dr Ure recommends that, upon coming out of the acid bath, instead of washing them as in Berthollet's process, they should be plunged while still wet with the acid liquor into hot soap-water. The soap is decomposed by the acid, the resulting muriate of soda is carried off by successive washings, and the oil of the soap, being absorbed by the fibres, gives them pliancy and softness.

Blueing.

When a perfect white is attained, a blue tint is given in the following manner. A quantity of the oxide of cobalt reduced to a subtile powder is diffused through a little clean water. Some of the water thus charged is drawn off and passed through a silk search into a small tub filled with the most limpid water, and when the workman judges by a trial made on a handful of thread that the water is sufficiently charged, he passes through it all the threads or goods in succession, taking care to add blue from time to time to make the shade uniform. The yarn is now carried to the wringing frame, and then dried in the open air.

The preparation is the same for piece goods, for gauzes, and linens, but in some cottons a little starch is added to the water containing the azure blue. Cambrics are usually passed twice through the blue, letting them dry between each operation.

General
view.

(743.) The following number and arrangement of the processes is given in Dr. Ure's edition of Berthollet's *Treatise on Dyeing*. A solution of potash must be made in the proportion of 40 measures of water, each weighing 16 pounds, to a quintal of potash, and 1250 pounds of thread.

The linen or hempen yarns, having been steeped in water for three days, and well washed, must be submitted to the

First ley.—20 measures of solution of potash, three hours boiling. The ley on cooling being as thick as a jelly.

Second ley.—For completing the removal of as many of the colouring particles as possible. This ley contains 10 measures of solution, and the boiling lasts for two hours.

Washing.—To carry off the ley and the colouring particles which it has dissolved.

First immersion.—Liquor at 2°; that is, of such strength that one measure of liquor dissolves two measures of solution of indigo. The immersion is continued till the yarn no longer weakens the liquid, after it is restored to its standard strength.

Washing.

Third ley.—12 measures of solution, three hours of ebullition.

Second immersion.—Liquor of the same strength as the first.

Fourth ley.—8 measures of solution, two hours of ebullition.

Third immersion.

Washing.

Fifth ley.—5½ measures of solution, two hours of ebullition.

Fourth immersion.—The liquor is brought down to 1°.

Washing.—At this period the white is usually manifest.

Acidulated water.

Washing.

Sixth ley.—5½ measures, two hours of ebullition.

Exposure on the green for six days.

Washing.

Fifth immersion.

Washing.

Acidulous water.

Washing.

Seventh ley.—4½ or 5 measures, one hour of ebullition at least.

Sixth immersion.

Washing.

Acidulous water.

Washing.

Ley and soap.—3 measures of solution. To this 8 pounds of black soap are added; and the solution is heated until the hand cannot be borne in it. When the soap has penetrated thoroughly, the process is stopped

Exposure on the grass, three days.

Blueing.

After this operation, the bleaching is finished, the thread is wrung out, and is set to dry.

The operations are the same for linen cloth, only they must be preceded by the ungumming. And for cotton in hanks the same order of processes is also proper. The exact number of the operations is of course not determinate, they must be continued if the goods are not sufficiently whitened, and depend greatly upon the judgment of the person who superintends.

(744.) *Bleaching for calico-printing.*—In calico-printing, a perfect white is not required, it being necessary only to remove the colouring matter and vegetable oils. It is generally first rinsed and then steeped in warm water for a day or two, and afterwards well washed and boiled in potash ley five different times.

Bleaching
for calico-
printing.

For 2000 pounds original weight of cloth, 1000 gallons of water, and from 40 to 45 pounds of potash are employed each time. The boiling is continued 8 or 10 hours. Between each operation the cloth must be well washed, and, after the third and fourth boiling, it must be spread upon the grass, or steeped for a night or two in a weak solution of chloride of lime. After this it is immersed for a few minutes in warm dilute sulphuric acid, and then is well washed, and dried.

The common process for bleaching cotton cloth, when fixed colours are previously dyed in the yarn, is first to wash the starch and dressing out in cold water, then to boil the goods gently in soap, and, after again washing, to immerse them in a solution of the chloride of potash. These processes are repeated several times until the white is good, when they are soured in dilute sulphuric acid.

Pullicates, or gingham, which have been woven with yarn previously bleached, are first freed by washing from the starch or dressing, then slightly boiled in soap, rinsed in pure spring water, and soured.

(745.) *Bleaching muslins.*—In bleaching the coarser kinds of muslin, termed jaconot muslin, they are, after the process of steeping, boiled in a weak solution of pot and pearl ashes; after being again washed, they are twice boiled in soap alone, and then soured in very dilute sulphuric acid. They are then again washed, boiled in soap, and immersed in the chloride of potash. The boiling in soap and steeping in the chloride of potash are repeated until the muslin is a pure white, when they are soured, and washed in pure spring water.

Bleaching
muslins.

The finer fabrics of muslin, such as those kinds called mull and book-muslin, are bleached in the same manner as the jaconot, except that, on account of the fineness of

Manufactures.

Silk bleaching.

the fabric, no pearl ashes are used in the boiling, but soap only.

(746.) *Bleaching silk.*—This kind of bleaching is generally performed in the dye-house, and is thus described by Mr. Packer, in his *Dyer's Guide*. "The silk is divided into hanks, each hank being tied with a piece of string; several of these are tied together (a handful of them) by putting a piece of string through each separate skein, and tying the piece of string in a long tie, to slip easily when they are wanted to be untied.

"A liquor is prepared of thirty pounds of **WHITE** soap (dissolved in water) to a hundred pounds of silk; the soap is cut into small pieces and boiled in water; when it is dissolved, the fire is damped.

"While the liquor is preparing the skeins of silk are put on rods; as soon as the soap-liquor becomes a little below boiling heat, (for it should not boil, as boiling would tangle the silk,) the silk is to be put into it in an oblong copper, being nearly full; it is to remain in the liquor till its gummy matter has left it, which will be seen by its whiteness and flexibility. It is then turned end for end on the rods, that the part above the liquor may undergo the same operation. As soon as this is accomplished, the silk is taken out of the copper, the hanks which were first turned being soonest done.

"The hanks are now to be taken from the rods to the peg, disentangled, and nine or ten of them put on one cord, this cord passing through the string that ties each hank. When the whole is corded, it is put into pockets of coarse strong white linen, fifteen inches wide and five feet long, closed at each end and on one side; when the silk is put in, the pocket is sewed all along the other side with packthread, and fastened with a knot; four pockets will hold the whole hundred pounds.

"The pockets being thus ready, another liquor is prepared like the first. When ready, and the boiling checked with cold water, the pockets are put in and boiled well for a quarter of an hour, checking with cold water in order to prevent its boiling over; it is necessary also to turn the bags about often with a pole, or rather let two persons have a pole each for this purpose. This operation is called boiling."

In addition to the processes of boiling with soap, as above directed, Mr. N. Kirwan recommends that the silk should be winched through a copper of water at the heat of 160°, having two pounds of soda (barilla) dissolved in it; then winch or wash in water, and wring and dry. In boiling silk intended to be dyed with common colours, 20 pounds of soap will do for 100 pounds of silk; but when the silk is ungummed, it should boil for three hours and a half, water being added to supply the evaporation. Silks intended for the greatest degree of white, either to remain white, or for delicate colours, are boiled twice in soap and water, and those that are intended for ordinary colours are boiled but once, and with a smaller quantity of soap, because the little remaining redness is by no means prejudicial to many colours. Different qualities of soap are, however, necessary for different colours. When the silks are boiled they are taken out of the copper and placed in a long shallow trough, that the water may run away from them. They are then examined, and such as have yellow or lemon-coloured spots remaining are boiled again for some time until the spots are removed. The silk has now to be whitened, the process for which is different according to the white which is intended to be given it, of which

there are five kinds, termed *China white*, *India white*, *thread or milk white*, *silver white*, and *azure white*. A copper is prepared with 30 parts of water in which half a pound of soap is dissolved, and to prepare *China white*, a little prepared annatto is added, and for the remaining whites, azure in different quantities. The silk, being put on rods, is now put into the copper, and kept turning end for end without intermission until the thread is uniform. The silk whitened for some purposes is sulphured; it gives it a rustling which for some things is esteemed; but silks intended to be dyed must not be sulphured. The sulphuring is done in the following manner. The hanks are hung upon poles in an appropriate room, provided with openings for the dissipation of the sulphuric fumes when the workmen are required to enter, but must admit of being perfectly closed, so as to admit no escape of the sulphur when the goods are placed in it. The brimstone coarsely powdered is placed in an earthen pipkin, with a little lighted charcoal at bottom, under the hanks of silk, and the room is closed all night. Two pounds of roll brimstone will sulphur a hundred weight of silk.

Silks for lace, gauze, &c., are neither boiled nor ungummed, those which are naturally whitish being used for such articles. It is sufficient to dip the silks in warm water and wring them; then sulphur and azure them. They must afterwards be again wrung and sulphured a second time. The Nankin silk requires no whitening.

Description of Apparatus, with Remarks on Leys and Immersions.

(747.) Having in the preceding section given the reader a general idea of the modern processes of bleaching, we shall now enter into a few particulars, which could not be very well introduced in the general description without interrupting the connexion of the several steps which it was thought desirable to preserve; for the same reason we have not yet alluded to the apparatus which are employed to facilitate the different processes.

Bucking, which as we have seen is the first important process, is now generally in England performed by the apparatus represented in plate lii. fig. 1, which was invented by Mr. John Lowrie, and is admirably calculated for conducting this operation on the large scale; at the same time it effects a considerable saving in the quantity of alkali employed.

A is the boiler, which is filled with the alkaline ley, and B B is a kieve situated above it, in which the goods to be operated upon are placed. This kieve has an upright C C situated in the centre of it, which is furnished at the upper part with a circular metal plate D D. E E is a pump connected at the lower end with the boiler A, and has a projecting tube or spout from it, which terminates exactly over the upright C C. The operation will now be readily understood; the boiler being filled with cold ley, the pump is set to work by the Machinery, a constant stream is flowing through the projecting tube upon the plate D D, which spreads it equally over the cloth. The ley, after it has soaked through all the cloths, is admitted by a valve F again into the boiler, to be again returned by the pump on the upper surface of the cloths. Immediately the pump is set to work, a fire is put to the boiler, by which the ley becomes gradually more heated every time it passes through the cloths, which is found, as before stated, to

Mechanical Processes.

Bucking apparatus. Pl. lii. Fig. 1

Manufactures.

be more effectual in removing the colour than when admitted hot upon them. When the ley begins to boil, the pump is disengaged from the Machinery, as the ley, being completely confined in the close boiler, finds its way up the tube without any assistance.

This apparatus unites the advantage of leying in much less time at a boiling heat, and with less consumption of fuel; for, instead of having to heat a ley incessantly cooled by the transfer, and which occupies the capacity of both the kieve and the boiler, the latter alone is filled, while the heat is preserved during the running, by the agency of the vapour.

Preparation of Leys.

Preparation of leys.

(748.) The preparation of leys is a department of bleaching which requires particular attention, and the defective manner in which it is sometimes executed is the most frequent cause of the weakening of the substances subjected to bleaching. It is necessary to know the exact quantity in each ley so as to be able to graduate its respective force, and to proportion it to the quantity and nature of the materials to be bleached. As the wood-ashes, soda, and even different species of potash, all contain a mixture of earths, salts, and alkalis, their weights are a bad criterion of their quality, nor is the areometer a surer test, since the salts mixed with the alkali also act upon it.

Home, who was aware of the necessity of estimating exactly the strength of leys, attempted to determine the quantity of alkali contained in the different substances employed by bleachers, by saturating them with an acid, but the means of analysis then known did not enable him to do it with any precision. The following is the process employed by Welter, the principle of which, like that of Home, is saturation with an acid. To render the different trials comparative, the acid must be of a degree of concentration which is uniform and easily ascertained; sulphuric acid, diluted with water till it is brought to a determined point of concentration, answers very well, and this degree of concentration may be fixed by saturating a certain weight of the acid with a fixed weight of fine, pure chalk dried at the heat of boiling water. If these analyses were made on pieces of potash taken at random from the barrels, only ambiguous results would be obtained, because in the same barrel there are often different qualities; it is therefore advisable that the experiment should be made only on solutions prepared on the large scale as leys, and always with the same weights of alkali to the same number of measures of water. The most expeditious way of making this solution cold is to suspend the potash at the surface of the water in an iron vessel pierced with a great number of holes, or formed of coarse iron wire. They should not be drawn off till it is certain that the whole of the potash is dissolved, and till by agitation the liquid is rendered uniform.

To make the experiments, it is necessary to be provided with a goblet, a glass rod, a small glass measure, and a tube, having as many times the capacity of the small measure as there are to be measures of water employed to one quintal of potash. These little apparatus are represented in fig. 2, 3, 4 of the plate lii.

The tube must first be filled with a solution of potash, and transferred into the goblet; it must be then filled with the test acid, which is also poured into the goblet, the mixture agitated with the glass rod, and a

trace drawn by it on a slip of paper stained with litmus. If the trace do not become red, another measure of the test acid must be added to the goblet, and, after the mixture is well stirred, a second trace should be made by the side of the former. If the paper is not then affected, the operation must be repeated by adding other measures of the acid until a red trace is at last produced.

In comparing the qualities of several potashes, it is obvious that is the best which has required the greatest number of measures of acid to produce a red streak, since it is the one which saturates most acid. The relative qualities of the different species of potash may thus be expressed numerically, by the number of measures of acid which each of them has saturated, which in fact amounts to counting the number of traces made on the paper, taking the first for as many as the tube contains of little measures, and adding unity for each of the following marks but the last, which should not be reckoned, because its colour indicates that it is beyond the term of saturation.

To obtain suitable variations of the leys, it is convenient to have solutions of potash of uniform strength, one, for example, with which an equal number of measures of test acid and solution of potash are required to produce saturation; but, whatever be the value of the potash, its solution may be brought to this point by adding to it for every quintal of alkali as many measures of water as there were measures of acid required to effect saturation on the quantity primarily employed. Hence the number of measures of water forming the solution ought always to be equal to that which expresses the standard of potash.

If in an assay it should happen that the first trace was red, it would be necessary to add measures of the solution instead of measures of acid, and, hence, potash should be added to the solution to bring it to the fixed degree of concentration.

Another method, recommended by Dr. Higgins, for ascertaining the purity of potash, is to take a given quantity of the alkali, and dissolve it in twice its weight of boiling water, stirring the mixture during the solution of the salt; while yet warm, it must be filtered through unsized paper. When all the liquor has passed through the paper, a very small quantity of cold water is gradually poured on the saline residuum on the filter, in order to wash out the remainder of the alkali. The undissolved salt remaining in the filter is sulphate of potash, which must be carefully taken off, dried, and weighed, in order to ascertain its quantity. To determine whether any common salt is contained in the alkali which has been filtered, evaporate the clear solution a little in a sand-bath, and set it in a cool place for twenty-four hours, at the end of which time any common salt it may contain will be found crystallized in the form of regular cubes at the bottom of the vessel. The sulphate of potash and common salt, being dried, weighed, and deducted from the weight of the crude alkali employed, will give the precise weight of the pure alkali it contains.

It is considered advantageous by some Chemists to render the alkali caustic; it has been proved (*Ann. de Chem.* tom. vi.) that in this state alkalis dissolve a fourth more of the colouring matter than when they are carbonated; the most general practice is, however, to use the ley in a mild state, from an idea that the time employed injures the stuffs. Berthollet remarks that this effect must be ascribed solely to the increased energy

Mechanical Processes.

Plate lii.
Fig. 2, 3, 4.
Methods of
ascertain-
ing the

potash.

Use of
caustic
alkali.

Manufac-
tures.

acquired by the alkali, the consequences of which may be prevented by a diminution of quantity.

To render the ley caustic, lime newly slacked is put into a large tub; the solution of potash is poured over it; the mixture is well stirred together, and after settling the clear liquid must be drawn off by means of a siphon. The residuum is then to be washed two or three times, and the washing added to the ley. One part of lime is sufficient to render two parts of potash caustic; these proportions ought, however, to vary with the qualities of the potash, and it is proper to ascertain that the proportion of lime is not too great, because the property which this substance possesses of precipitating the colouring matter held in solution by the alkalis may render an excess of it injurious. On this account, some solution of potash is to be mixed with the liquor floating over the lime in the tub in which the potash is made caustic. If it become turbid it contains lime in solution, and solution of potash must therefore be added till it no longer yields a precipitate.

According to the experiments of Kirwan, *Ann. de Chimie*, tom. vi., the use of alkaline sulphurets might be tried. They have, indeed, the inconvenience of producing spots in places which come in contact with metals; but these will disappear by employing in the last leys an alkali free from the sulphurets, or by passing them at the end of this bleaching through acidulated water. The following is the order in which this celebrated Chemist has classed, according to their energy, the substances possessing the faculty of dissolving the colouring matter of flax:

1. Alkaline sulphurets.
2. Caustic potash.
3. Caustic soda.
4. Carbonate of potash.
5. Carbonate of soda.

Kirwan appears to have considered that lime water dissolves but very little of the colouring matter, which he ascribes to the small solubility of lime; but, independently of this cause, it is not probable that lime, which forms an insoluble combination with colouring matter held in solution by potash, could of itself dissolve it. He observes, that sulphur does not augment the solvent faculty of lime; Dr. Higgins has, however, stated that there is a remarkable economy in employing sulphuret of lime in bleaching, and, as proposed by him, it was extensively employed for one or two years by the linen-bleachers of Ireland. The goods, Dr. Ure remarks, were much injured by this article, but whether from its injudicious use, or otherwise, does not appear. This compound, he further remarks, however, has been recently tried in some establishments with advantage. We conclude these remarks on this process of bleaching by a Table giving the quantity of alkali in the following substances:

	Real alkali in 100 parts.	
Best American pearl ashes	60 to	73
Caustic American potashes in reddish lumps.	60	63
Second American in grey lumps	50	55
Second American pearl ashes	50	55
White Russian pearl ashes	52	58
White Dantzic ditto	45	52
Alicant barilla	20	23
Inferior kinds of barilla	10	15
Natron	20	30
Salt of tartar of the shops	0	72

Immersion in Chlorine.

(749.) This forms, as we have seen, the great distinction between the old and new process; but although every one admits the advantages of the latter, yet some difference of opinion exists as to the best way of applying it. Some Chemists recommend combining the chlorine with potash, some with lime, while others seem to prefer using it without either; but, before offering any remarks on these subjects, it will, perhaps, be well to describe the apparatus employed in each case. In plate lii. fig. 5, 6, are sections of a very complete Machine employed by Berthollet, which, with little variation, may be adapted to the preparation of any of the substances employed. The same letters apply to both figures: A is a furnace containing an iron vessel F, in which is placed the matrass containing the mixture from which the gas is produced; B is the second part of the apparatus, termed the receiver, which is made of strong oaken staves hooped with iron and covered with cement. Between the matrass and the receiver is a bottle H, in which water is placed. It has three tubes inserted into it, of which one G forms the communication with the matrass, the second K conducts the gas into the receiver, and the third S, which is open at both ends, is for the purpose of admitting air when a partial vacuum is formed by the vessels becoming cool, and is termed the tube of safety. It must be carried higher above the water in the bottle than any part of the conductor tube, otherwise the water, when pressed upon by the gas, would escape at its upper part. The portion of this tube which dips into the water of the bottle should be shorter than that of the conductor tube, which is above the level of the water in the receiver, so that when the vessels become cool, and a partial vacuum formed, the external air may enter by the tube of safety before the water of the receiver can rush in through the conductor tube.

The interior of the receiver is furnished with three inverted tubes L L L, to receive the gas extricated from the matrass, which are secured by transverse bars fixed to the circumference of the receiver; any fastenings of iron would not answer the purpose, as they would be attacked by the chlorine. The spaces between the tubes and sides of the receiver are closed, with the exception of openings which permit the liquor to pass from one tub to another, and which are placed alternately on opposite sides, as may be seen in the figure. P P P are tubes which permit the gas to pass from one tub to the one above it, when the strata of it exceeds in thickness the length which the tubes project beneath the superior tub. The tube of the upper shallow tub is made of considerable length, as shown in the figure, in order to disperse the gas, which being undissolved in the water would be diffused in the air, and annoy the workmen.

I is the immersion tub in which the goods are placed after the bucking process; it receives the liquor by a siphon R, which is placed in a tube T, leading to the bottom of the vessel B, in order that the most concentrated acid may be conducted into the immersion tub.

It is useful to attach to the upper tub a pipe with a bent extremity, dipping into a vessel filled with a solution of potash, so that in the event of the gas filling the cavity of the tub, the excess escapes by this pipe and is absorbed by the potash, thus protecting the manufactory from the inconvenience that would result from its diffusion.

Manufactures.

The operation of the apparatus is as follows. After mixing the ingredients in their proper proportion, they are introduced into the matrass, which is then placed in the sand-bath, the sulphuric acid, previously diluted and cooled, is poured into it, and the tube of communication fitted to the orifice of the matrass. The ascent of the water of the intermediate bottle, in the tube of safety, will denote if the joints are air-tight; but this may be further ascertained by presenting to them the moistened stopper of an ammonia bottle, which will cause any portion of chlorine gas which escapes to become manifest by a white vapour. The fire may be kindled in the furnace before placing the matrass in the sand-bath, taking care that the heat is not so great as to endanger the matrass being cracked when set into it. The whole apparatus, however, may be arranged before lighting the fire; the heat is then to be very cautiously raised, till the intermediate bottle ceases to be filled with yellow vapours, and the conductor-pipe begins to grow warm, when the fire must be extinguished. Some attention must, at the same time, be paid to the receiver, the inverted tubs must be so adjusted as to be covered with water, (except the upper one,) and care must be taken to extract all the air, which may be done by a siphon introduced into the side opening.

Proportion of ingredients.

(750.) The proportions of the ingredients to be employed for the generation of the gas is a subject upon which considerable difference of opinion exists. The most important ingredient is oxide of manganese, which generally contains about 44 parts of the metal to 66 of oxygen, but as taken from the mines is generally found combined with other substances. The principal defect arises from its being combined with chalk or oxides of iron, which, when mixed with it in considerable quantities, very much weaken the bleaching property of the liquor. Before the proper proportions of the ingredients can be known it is necessary to analyze the manganese. The presence of the carbonate of lime may be known by pouring on the manganese nitric acid diluted with eight or nine parts of water; and if the manganese be good no effervescence will ensue, nor will the acid dissolve any thing, but if carbonate of lime be present it will be taken up by the acid. If to the solution a sufficient quantity of carbonate of potash be added to precipitate the lime, its weight will show how much chalk the manganese under examination contains. When oxide of iron is mixed with the manganese it is less easily discovered, but, if the iron be in such a state of oxidation as to be soluble in muriatic acid, the following process may discover it: Dissolve a portion of the manganese in strong muriatic acid with the assistance of heat, dilute the solution largely with rain-water, and add a solution of crystallized carbonate of potash. The manganese will remain suspended by the excess of carbonic acid, but the iron will be precipitated in the state of coloured oxide.

When the properties of the oxymuriatic acid, or chlorine, were first discovered, the first attempts at its application were very naturally made without combining it with any other substance. It was, however, found, in consequence of its slight affinity to the water, that so much vapour was given out, that the health of the workmen was much injured. This led to various attempts at combining it with other substances; and, soon after the practice of the new bleaching had begun to be established, a liquor, about which considerable mystery existed, was prepared at Seville, known under the name

VOL. VII.

of the lixivium of Seville, which was a combination of oxygenated muriatic acid with a certain proportion of fixed alkali. This liquor can be imitated by employing the following proportions for the distillation of the alkaline solution: muriate of soda 77 grammes, sulphuric acid 61 gr., oxide of manganese 30 gr.; the gas disengaged from these materials is received in a litre of water, in which 120 gr. of common potash or soda have been dissolved. This liquor is to be diluted for use with 10 or 12 parts of water. To diminish the offensive smell of the oxygenated muriatic acid, Des-croizilles mixed with it carbonate of lime or chalk.

Mechanical Processes.

These proportions do not materially differ from those very commonly employed at present. In Glasgow, which is the chief seat of bleaching and dyeing in Great Britain, the common proportions are equal parts of salt, manganese, sulphuric acid, and water; and in Ireland they are said to be nearly the same. Berthollet recommends 10 parts of oxide of manganese, 20 parts of sulphuric acid, and 27 muriate of soda; and Mr. Rupp, of Manchester, 3 parts manganese, common salt 8, sulphuric acid 6, water 12. These proportions, however, so much depend upon the quality of the substances employed that it is impossible to give any precise rule for them.

In the year 1798, Mr. Charles Tennant, by a well-conducted series of experiments, showed that oxymuriatic acid might be combined with the alkaline earths; lime being most readily procured, he employed that substance, and found that, by Mechanical agitation, it readily united with oxymuriatic gas, and became thereby dissolved, forming a pure and transparent solution of oxymuriate of lime, possessing the same power of retaining the gas as belongs to the alkalis.

Mr. Tennant has since carried his improvement to a greater degree of perfection by combining the oxymuriate with the quick lime in a dry state, and thus rendering it portable to any distance at a small expense. For use, the concrete oxymuriate of lime is diffused in water by agitation, and the insoluble matter contained in the lime is allowed to subside until the liquor is transparent. When drawn off for use it is further diluted with water before the goods are immersed in it.

Berthollet, in his excellent Work upon dyeing, enters into a comparison of the relative value of these different preparations, and of the nature of their Chemical action on the oxygenated muriatic acid.

The action of the water, he remarks, being very feeble, there may be obtained from it its whole sensible effect, retarded and modified at will according to the concentration which is given it. The alkalis exercise a much more powerful action on it than water does, and thereby can give a much greater condensation, repressing almost entirely its smell.

The advantages presented by the oxygenated muriate of potash, or soda, are, first, to require a less complex apparatus, for it is sufficient to employ a receiver containing the alkaline solution, in order to condense the oxymuriatic gas, with the single precaution of plunging the conductor-tube to the bottom of the receiver, and receiving the gas under a tub; secondly, to repress almost entirely the suffocating odour of the gas; thirdly, to furnish the agent of oxygenation much more condensed under the same volume, and, consequently, to render it of easier and less expensive carriage; and, lastly, to produce its effect somewhat more speedily. It has, however, these disadvantages: when a fixed

3 x

Manufac-
tures.

alkali acts on oxymuriatic acid, a portion of the acid is merely condensed, which retains the proportion of its elements, and the properties dependent on the tendency which they preserve to enter into other combinations. Another portion is decomposed, and the result of the two new combinations, which are established in its stead, gives from 5 to 6 parts of muriate of potash for 1 of super-oxygenated muriate of potash, a salt which contains nearly 0.38 of its weight of oxygen. Now the oxygen present in the last combination is so fixed down that it can no longer attack the colouring particles, nor resume the elastic state by the action of light. The whole of the oxymuriatic acid which suffers this transmutation of combination is, therefore, lost for bleaching.

We thus perceive that the oxymuriates of potash and soda ought not to produce, in their agency on the colouring particles, so much effect as a simple aqueous solution, which contains, under the same liquid volume, a quantity of oxymuriatic gas equal to what has been condensed by the alkali.

Berthollet's
remarks on
the use of
lime.

(751.) The use of lime is evidently advantageous on point of economy, and its state of condensation and desiccation renders its carriage less expensive. But it has the inconvenience of transforming a portion of the oxymuriatic acid, and of containing the super-oxygenated muriate, which cannot be indicated in this combination by nomenclature, being precise only with regard to very uniform combinations; it appears even that the proportion of super-oxygenated muriate is considerable; for if, after expelling by a slight degree of heat the oxygenated muriatic acid, which had retained its properties, the remaining substance be examined, it is found no longer to produce discoloration; and if it be urged with a stronger heat in this state much oxygen gas is disengaged. Welter tells us that in his comparative experiments he had observed that the gas condensed by lime produced only one-tenth of the effect which may be obtained when it is received in water. The use of the oxygenated lime must, therefore, the author remarks, be disadvantageous; but it may be convenient for certain purposes, from the facility of carriage and preservation, where the economy of the process is of secondary importance. Under this point of view it merits the commendation which it has received.

On the pro-
cess of
washing.

(752.) We conclude this Notice by a few remarks on the process of washing, and on the Machinery usually employed for it. Whoever projects an establishment should examine if the place where he proposes to erect it unites the advantages of fabrication, commerce, and carriage; but above all he must have good water at command, for without this condition he will not succeed in obtaining a pure white. Muddy water, which leaves a blackish deposit, may, however, be employed with success, but water whose deposit is yellow always gives an unfavourable shade. These observations are particularly applicable to the bleaching of cotton, the white of which should have the greatest purity.

Immediately after each operation it is necessary, by careful washing, to discharge from yarns and stuffs the liquor with which they are impregnated: because, if it were carried into that of the next operation, it would neutralize a portion of it, and thus impair its action. This precaution, moreover, adds much to the perfection of the white.

To wash linen or cotton yarns, a workman takes a hank in each hand, plunges them in the water, agitates, withdraws, and replunges them for three or four times, seizing

the hank each time by a different part; he then puts the two hanks together, wrings, and throws them down.

Mec hanical
Processes.

(753.) The washing of piece goods is sometimes done by hand, with the aid of a rod or mallet, but it is more commonly effected by Machinery. The Machines usually employed in this country for the purpose are termed *wash-stocks* and *dash-wheels*.

Washing-
Machine.

The wash-stocks consist of large wooden mallets which are suspended upon pivots, and can be raised by wipers on a revolving shaft through a considerable arc. The cloth is laid in a piece of wood curved hollow, termed the *turnhead*, into which the mallets, when disengaged from the wipers, fall with considerable force. The turnhead and end of the mallets are made of such a shape that the cloth is turned partly round at each blow, at the same time an abundant stream of water rushes upon the cloth, through holes in the upper part of the turnhead. This mode of washing is, however, almost entirely given up in Lancashire, where a preference is given to the dash-wheels; but in Ireland and Scotland they are still much used. In the former Country they are very commonly made with double feet, suspended above and below two turnheads, and put in motion with cranks instead of wipers. Wash-stocks, properly constructed, make from 24 to 30 strokes per minute.

Wash-
stocks.

(754.) The dash-wheel is of more recent invention, and may be considered a very important improvement upon the ordinary modes of washing. A representation of one of these Machines is given in fig. 7, 8, of the plate Bleaching: A A A is a large wheel made of wood and secured with iron hoops. It is divided inside into four compartments, (as shown by the dotted lines in the figure,) which are closed up, with the exception of apertures B B, to admit and discharge the water employed in the cleansing and openings on the opposite side, where the cloth is introduced into the wheel. These are shown dotted in the figure at C C, &c. P P is the pipe by which water is supplied to the wheel; the nozzle of the pipe is directed so as to be exactly opposite the circular aperture in the wheel, and the water being under a pressure is forced into it, during every part of the revolution, and escapes by little openings left in the circumference. Motion is conveyed to the dash-wheel by the levelled wheel D D, situated on the shaft of the water-wheel or steam-engine, which engages a similar one on the shaft of the dash-wheel. The velocity of dash-wheels requires to be nicely regulated; when it is too slow the pieces of goods merely slide down the inclined planes of the partitions, and if too rapid they are held stationary at the circumference by the excess of the centrifugal force. Twenty-five revolutions per minute is considered the proper speed for a wheel of six feet diameter; some persons, however, suppose them to perform better with twenty-six or twenty-eight revolutions. Any considerable deviation from this velocity, however, impairs the utility of the Machine, or destroys its functions altogether.

Dash-
wheels.

Fig. 7, 8

(755.) After the cloth is washed by the dash-wheel the water is generally compressed from it by means of squeezers, which consist of a pair of wooden rollers, fixed in a cast-iron framing, the lower one of which receives motion from the mill. The upper one can be moved up and down in the frame by means of a lever, so that when the end of the cloth is introduced between the rollers, and the upper one pressed down upon the lower, it receives motion from it and draws the cloth in them, by which a great quantity of water is, of course, squeezed out.

Squeezers.

Manufac-
tures.

Various other methods of washing are made use of in different factories. On the Continent a method employed is very commonly as follows: two wooden rollers placed one above the other on frames are set in the direction of the breadth of a river, the upper one of which is fluted. The surface of the under roller is smooth, and carries a handle on the axle of one of its pivots. When goods are washed by this means, they must be thrown into the river, and the ends passed between the two cylinders. On turning the winch the cloth is drawn in between the rollers, and, being pressed down by the upper one, receives a small stroke every time a groove passes. Pieces passed in this way five or six times successively are very well washed.

A variety of other methods of performing the operation of washing might be described, which we do not, however, conceive it necessary to enter into, as they generally resemble in principle some one of the processes above noticed.

*Dyeing.*History of
dyeing.

(756.) The first attempts at impressing artificially colours upon objects to which they do not naturally belong were made at so early a period, that to expect to trace them to their original source must be wholly hopeless. That the Art owes its origin to the natural passions of Man for variety and finery there can be no doubt. The Savage, as well as the man born in the midst of civilization, is equally attracted by the splendour of coloured objects, and even in the former state attempts would be made to employ some of the ready means which Nature has placed within our reach to give colour to our apparel or utensils. As Society advanced in civilization, new methods would be invented and new materials called to our aid, till the Art of dyeing assumed, at length, that degree of importance which it now possesses, and by the practice of which thousands of human beings derive their daily bread; while many others have accumulated large and even princely fortunes.

That the first efforts of the uncultivated Savage would be rude and imperfect there can be little doubt; the colours he had been at considerable labour to obtain would perhaps be fleeting and perishable, while others would be permanent; this would naturally lead to renewed efforts and to new ideas, and although many of his first trials, made without the guide of fixed principle, might be, and naturally would be, failures, others might succeed, and thus gradually lead to the Art of dyeing.

Hindus' Art
of dyeing.

The Egyptians are amongst the earliest nations of whose skill in dyeing we have any authentic account, but it is extremely probable that they derived the Art from the Hindus, and the other inhabitants of India, who state, that they practised it from a very remote period: indeed, most of the ancient Arts and Sciences seem to have arisen in that quarter of the globe, and, although, on account of the political and religious institutions of these Countries, they never attained there any great degree of perfection, they gradually spread from this source amongst other nations less fettered by prejudice, and more disposed to adopt whatever might be regarded as real improvements. The natural fertility of India, and the great variety of materials which it affords for cultivating the Art of dyeing, were extremely favourable to its early progress; but religious prejudices and the unalterable castes of Society, as above observed, imposed restraints which interfered greatly with the

attainment of perfection. It appears, indeed, that the Art of dyeing cotton was in the same state when Alexander invaded the Country as it is even at this day, their processes being still so complicated, tedious, and imperfect, that they would be impracticable in any other Country, in consequence of the cost of labour they incur; in fact, European industry has far surpassed them in correctness of design, variety of shade, and facility of execution: and, if we are inferior in the liveliness of some few of the colours, it is solely to be ascribed to the superior quality of some of their dyes, or perhaps to the length and multiplicity of their operations.

Mechanical
Processes.

The Egyptians do not seem to have made any important additions to the knowledge of dyeing, which they borrowed from their Eastern neighbours, and indeed little could be expected from the genius and industry of a People who were strictly prohibited by the principles of their Religion from changing even the most indifferent customs. It appears, however, from Pliny, that they were acquainted with a mode of dyeing very much resembling calico-printing. He mentions that the Egyptians began by painting on white cloths with certain drugs, which in themselves possessed no colour, but had the property of abstracting or absorbing colouring matters; that these cloths were afterwards immersed in a heated dyeing liquor of a uniform colour, and yet, when removed from it soon after, they were found to be stained with indelible colours, differing from one another according to the nature of the drugs which had been previously applied to the different parts of the stuff.

Art of
dyeing
in Egypt.

The most celebrated colour among the Ancients, and that which appears to have been brought to the greatest perfection, was the purple. It was to chance alone, according to the traditions of antiquity, that they owed this discovery. A shepherd's dog, instigated by hunger, having broken a shell on the sea-shore, his mouth became stained with a colour which excited the admiration of all who saw it, and which was afterwards applied to stuffs with success; but there is some discordance in the details of ancient writers of the circumstances of this event. Some place the discovery in the reign of Phœnix, second King of Tyre, 500 years before Christ: others at the time that Minos the First reigned in Crete, about 1439 years before the Christian era. But the greatest number agree in giving the honour of the invention of dyeing purple to the Tyrian Hercules, who gave his first trials to the King of Phœnicia. The King was so jealous of the beauty of this new colour, that he forbade the use of it to all his subjects, reserving it for the garments of Royalty alone. Some authors, however, relate the story differently: Hercules' dog having stained his mouth with a shell which he had broken on the sea-shore, Tyras, a nymph of whom Hercules was enamoured, was so charmed with the beauty of the colour, that she declared to her lover that she would see him no more till he brought her a suit dyed the same. Hercules thought of a way to satisfy his mistress; he collected a great number of shells, and succeeded in staining a robe of the colour the nymph had demanded.

Purple of
the
Ancients.

Such are the different traditions handed down by the Ancients of the origin of the purple dye. They are evidently blended with fiction, yet they may serve to fix the epoch of this discovery. Whether this Tyrian purple was similar to that mentioned in Holy Writ, as used by Moses for the vestments of the High Priest and the ornaments of the Tabernacle, may admit of some dispute, since it is not certain, according to M. Huet, that the

Manufac-
tures.

word *argaman* of the Hebrew text, which all the interpreters translate by *purpura*, means in reality that colour.

This colour was so highly valued by the Ancients, that it was either consecrated to the worship of the Deity, or conceived to be fit only for the garments of Royalty. The Babylonians devoted this purple to the dress of the idols, and most of the other nations of antiquity seem to have done the same thing. Pliny informs us that it was used by Romulus and the succeeding Kings of Rome, as well as by the Consuls and first magistrates under the Republic. The Roman Emperors at last appropriated it entirely to their own use, and denounced the punishment of death against those who should dare to wear it, though covered with another colour.

This absurd and tyrannical restriction confined the dyeing of the Tyrian purple to a few individuals, and in a short time the knowledge of the process was entirely lost. In the XIIth Century neither the shell-fish which furnished the dye, nor the methods which the Ancients employed to communicate to cloths the rich and purple hue which it afforded, were at all known, and, on the revival of Learning, it was even suspected by many that the accounts which have come down to us respecting this celebrated colour were entirely fabulous. Notwithstanding the very high esteem in which the Tyrian purple was held by the Ancients, and the great encomiums which have been bestowed upon it by many of the Moderns, the loss of it is perhaps scarcely an object of regret. The shell-fish which furnishes this dye probably exists now in as great abundance as formerly. It has been so accurately described that it may be recognised, and it is in fact stated that shell-fish have been found near Nicoya, a small Spanish town in South America, which possess all the properties described by Pliny and other ancient writers. These shell-fish, it appears, are at present used in dyeing cotton on the coasts of Guayaquil and Guatemala. Cole in the year 1686 discovered some of them on the English coast, and Plumier found a species at the Antilles. Reaumur has made many experiments on the whelks which he obtained from the coasts of Poitou, and Duhamel has minutely examined the colouring matter of the purple shell-fish, which he found in great abundance on the coast of Provence. He observed, that this liquor does not take a purple colour without the action of light,—a circumstance which Reaumur had before remarked respecting that of the whelks: that, although at first white, it becomes of a yellowish-green, which deepens to a sort of blue; that it afterwards reddens, and in less than five minutes becomes of a very fine deep purple. In all respects the colour produced possessed the character of the ancient purple. If this method, therefore, of dyeing purple is no longer practised, it is not on account of our ignorance of the process, but because we are acquainted with more beautiful, as well as much less expensive, dyes; though, as Dr. Bancroft remarks, the purple afforded by the shell-fish in question may still be applied with advantage in topical dyeing, for which but little colouring matter is required.

Dyeing
amongst the
Greeks and
Romans.

The Art of dyeing seems to have made but little progress among the Greeks,—a fact which must undoubtedly be ascribed to the little estimation in which the Arts that contribute to conveniency or luxury alone were held by that warlike and high-minded People.

The Art of dyeing linen appears to have been unknown in Greece before Alexander the Great invaded

India, where, according to Pliny, his captains in skirmishing on the banks of the Indus first saw, to their astonishment, the enemy changing the ensigns of their vessels, and suddenly displaying others of different colours. Even the dyeing of woollen stuffs seems to have made but little progress at that time, as the same author, after declaiming against the luxury of his contemporaries for wearing cloth dyed of colours which rivalled those of the finest natural flowers, observes, that none of these flowery colours were in use during the time of Alexander. It is probable, however, that the companions of that conqueror brought back from Persia and India some information respecting the rich dyes employed in those Countries, which they afterwards diffused among their Countrymen.

Mechanical
Processes.

It appears to have been from the Greeks that the Romans derived all their knowledge of dyeing; they imbibed in some measure from them the same feeling of contempt with regard to the Art, so that not much progress was made during their time. They appear, however, to have set a very high value upon a red colour, from an insect termed *kermes*, or *Coccus ilicis*. Pliny mentions that this colour was sometimes employed by them, with the colour of *murex* and *baccinum*, (the shell-fish which gave the Tyrian purple,) in producing a sort of purplish-crimson called by the Romans *hyssginum*.

The first discovery and application of the colouring property of this insect in the Art of dyeing does not seem to be known. A species of the insect is mentioned by most of the ancient Hebrew, Greek, Latin, and Arabian writers, but we see nothing of its application to dyeing. Pliny states that *kermes* was procured from both Asia and Africa, from Attica, Galatia, Cilicia, and also from Lusitania and Sardinia, but those produced in the last-mentioned place were of the least value. Pausanias says they were to be found in Phocis. As the *coccus* is likewise mentioned by Moses and other Hebrew writers, *kermes* must have been also met with at that period in some of the remote Countries of the East.

It is uncertain whether the Romans understood the use of alum as a mordant. Pliny describes several species of alum, of which the island of Cyprus afforded two, one white and the other black; the white alum, he adds, is principally used for dyeing wool with clear and bright colours; the black for dyeing brown and dark colours. Beckmann supposes that the alum of the Ancients was very different from the triple compound to which the Moderns apply the term alum, which seems to be very probable.

Use of
alum by the
Ancients.

The Romans appear to have had various other colours besides the two principal ones above mentioned. It was customary among them from the earliest times for newly-married women to wear a yellow veil,—a colour which was confined entirely to matrons; and those who were employed in the Games of the Circus were distributed into divisions, each of which were dressed in an appropriate colour. The colours mentioned are *color prasinus*, green: *rufatus*, orange: *venetus*, grey, or perhaps a light blue and white.

The following seem to be the principal substances from which these colours were obtained. *Alkanet*, or the roots of *Anchusa tinctoria*, the blood of birds; the *Genista tinctoria*, or dyers' broom; madder; woad; the bark of the walnut, and pods of the Egyptian acacia.

These are the chief substances which are mentioned to have been employed by the Romans; many more were very probably in use at that time. Indigo (*Indigum*

Manufac-
tures.

nigrum) is mentioned by Pliny, and although some doubts have been entertained respecting the true nature of this substance, some supposing it to have been Indian ink, yet it is very probable he meant the indigo of the Moderns, from the purple smoke which he describes as emitted when set on fire. It is also doubtful whether this substance was employed in dyeing, or merely as a pigment. See Indigo Works.

The two substances, woad and madder, are used to considerable extent in the present dyehouses. The first origin of woad as a dye we cannot find any mention of, but its properties were very probably known at a very early period. Madder is mentioned by Dioscorides; at least he describes a plant called *ereuthodanon*, which is supposed by Beckmann to be the same.

The fruit he states is at first green, then red, and lastly black. The thin long roots, he further states, were employed in dyeing, and on that account the cultivated kind was reared with much benefit in Galilea, around Ravenna in Italy, and in Caria, where it was planted either among olive trees, or in fields destined for the purpose.

Scarlet dye.

Among the most important steps in dyeing may be classed that of the discovery of the scarlet dye. The origin of the term scarlet, from which we might judge of the time of its invention, seems very uncertain. Stiler says scarlet is entirely German, and compounded of *schor*, the fire, and *lacken*, cloth, so that its real signification is fire-cloth, or fire-coloured cloth; while Reiske, on the other hand, considers that the word is originally the Arabic *scharal*, which means the kermes dye. There is no doubt that the colour must have been known at a very early period. Beckmann quotes a passage from the *Historica Gebrica* of Pontanus, in which it is stated, that Henry III., in the middle of the XIth Century, conferred upon the Count of Cleves the Burg-graviate of Nimeguen, on condition of his delivering to him yearly three pieces of scarlet cloth made of English wool.

Of the preparation and goodness of the ancient scarlet we certainly know nothing, but, as we find in many old pieces of tapestry of the XIth Century, and perhaps earlier, a red which has continued remarkably beautiful even to the present time, it cannot at any rate be denied that our ancestors have not extolled their scarlet without reason.

Discovery
of cochineal.

This colour was, however, very different to that which bears its name in the present day, the former having been obtained from kermes, while the latter is procured from cochineal, and exalted in brilliancy by the application of a particular mordant. The insect to which we give the name of cochineal was unknown in Europe before the discovery of America. When the Spaniards first visited Mexico, in the year 1518, they observed that the inhabitants of that Country employed cochineal for communicating a colour to some parts of their domestic utensils, ornaments, &c., and also as a dye for cotton. The Europeans were so struck with its beauty that an account of it was transmitted to the Spanish ministry, who, accordingly, in the year 1523, ordered the Cortes to adopt proper measures for increasing the produce of a commodity which appeared to be of the utmost value as a dye.

Discovery
of Cornelius
Drebbel.

The tincture of cochineal alone yields a purple colour not very pleasant, which may be made into a most beautiful scarlet by a solution of tin in *aqua regia*. Mr. Ruhlenskamp at Bremen, one of the most learned dyers in Germany, and who has studied with great care every new improvement of the Art, gives the following

history of the modern scarlet dye. The well-known Cornelius Drebbel, who was born at Alkmaar, and died in London in 1634, having placed in his window an extract of cochineal, made with boiling water, for the purpose of filling a thermometer, some *aqua regia* dropped from a phial broken by accident which stood above it, and converted the purple dye into a most beautiful dark red. After some conjectures and experiments, he discovered that the tin which had been dissolved by the *aqua regia* was the cause of the change. He communicated his observation to Kuffelar, an ingenious dyer at Leyden, who was afterwards his son-in-law. The latter brought the discovery to perfection, and employed it some years alone in his dye-house, which gave rise to the name of Kuffelar's colour. In the course of a little time the secret became known to an Anabaptist called Gulich, and also to another person of the name of Van der Vecht, through whom it became known to the celebrated Giles Gobelin, at Paris, who there erected a large dye-house. About the year 1643 a Fleming, named Kepler, established the first dye-house for scarlet in England at the village of Bow, near London, on which account the colour was called at first Bow dye.

(757.) In England the Art of dyeing now began to excite some attention. At a meeting of the Royal Society on the 30th of April, 1667, Dr. Hook was appointed to translate into English a Work entitled *Plictho*, which had been published about a century before in Italy. At the same meeting Sir William Petty, one of the earliest and most active Members, in consequence of a previous request of the Society, laid before them *An Apparatus to the History of the Common Practice of Dyers*, which was afterwards printed in Dr. Spratt's *History of the Royal Society*, and seems to have been the first Work published in the English language on the processes and operations of dyeing. Nearly two years afterwards Mr. Boyle presented to the Society an account of his experiments on colours. Dr. Hook, at a meeting of the Society on the 11th of November, 1669, produced a piece of calico dyed by a method invented by him; he was in consequence directed to pursue the inquiry with respect to other colours, and accordingly in the following month he procured another piece dyed with yellow, blue, green, and purple, which he said might be washed with warm water and soap without removing the colours. From this time, nothing of importance seems to have been done by men of Science in this Country towards the improvements of the Art of dyeing or calico-printing for nearly the space of a century.

In France the minister Colbert, anxious to extend the commerce and manufactures of his Country, which had languished during the stormy administrations of Richelieu and Mazarin, turned his attention particularly to the Art of dyeing. He established several manufactories, and invited the most skilful artists to superintend them. It is remarkable that those of Vaurobais and Sedan were entitled, in the letters patent, "Manufactories of Fine Cloth after the Dutch and English fashions." In 1762 he published a Table of instructions for dyeing, under the title of *Instruction Générale pour la Teinture des Laines et pour la Manufacture des Laines de toutes Nuances, et pour la Culture des Drogues qu'on y emploie*. This Work was of great importance, as it was not only intended to diffuse information, but as a legislative act to control the dyers in their operations.

Dufay's
Works on
dyeing.

In the year 1739 Dufay published a new set of instructions under the administration of M. D'Orry. He appears to have been the first who entertained just notions of the true nature of colouring substances, and the cause of their adhesion to stuffs when dyed. In his *Observations Physiques sur le Mélange de quelques Couleurs dans le Teinture, Mém. de l'Académ.* 1737, he observes, that colouring particles are naturally disposed to adhere more or less firmly to the filaments which receive them, and he remarks that without this disposition stuffs would never assume any colour but that of the bath, and would always divide the colouring particles equally with it, whereas the liquor of the bath sometimes becomes as limpid as water, giving out all the colouring matter to the stuff, which he considers to indicate that the ingredients have less attraction for water than for the particles of the wool. He appears, however, to have had no idea of the important cause of the permanency of colours, which arises from the use of mordants or the interposition of a suitable basis, having a particular attraction for the colouring matter and dyeing substance, and acting as a bond of union between them. He examined with great sagacity certain processes, and established the surest methods that could at that time be employed for determining the goodness of colour, which he did in an easy and comprehensible manner. His labours on the whole entitle him to the gratitude of posterity, as he may justly lay claim to the merit of having laid the foundation of the true theory of dyeing.

Hellot's
Works on
dyeing.

We are indebted for one of the best practical Treatises on the Art of dyeing wool and woollen cloths to Hellot, who succeeded Dufay. This Work is valuable for the accuracy with which the numerous processes are described: he is said, however, to have suffered himself to be misled by vague and groundless hypotheses on the cause of the adhesion of colouring particles to the substance dyed, the action of mordants, and the difference between the durable and fading dyes. In all the processes of dyeing he conceived that a sulphate of potash was formed, and that this salt, being sparingly soluble in cold water, and little affected by air or light, first dilated the pores of the stuff, thus preparing it for the reception of the colouring particles, and afterwards wedged these particles so closely together that it became impossible for them to make their escape. This hypothesis, which was evidently not countenanced by sound reasoning any more than by fact, was admitted without proof, and regarded for a considerable length of time as the true cause of the adhesion of the colouring principle to stuffs. Notwithstanding, however, the erroneous views of Hellot, the inferences which he deduced from them were not without practical utility, and many of the processes which he recommended may be followed with the same advantage as if they had been derived from the most scientific principles.

It is surprising that Macquer, who was an excellent Chemist, and among the first who entertained correct ideas of the nature of Chemical affinity, should have been led away by the hypothesis of Hellot. He remarks, in his Treatise on dyeing silk, "I shall now explain the action of mordants, and unfold the causes of durable and fading dyes; but this subject has been treated with so great sagacity by Mr. Hellot, that I shall refer the reader to him."

Bergmann.

Bergmann seems to have been the first who referred the phenomena of dyeing entirely to Chemical principles.

Having dyed some wool and silk in a dilute solution of indigo in sulphuric acid, he explains the effects he observed in the operation, by the blue particles having a stronger affinity for the particles of the wool and silk than for those of the acidulated water; he remarks that this attraction of the wool is so strong as to deprive the liquor entirely of the colouring particles, and that the weaker attraction of the silk can only diminish the proportion of those particles in the bath; and he shows that both the durability of the colour, and the degree of intensity it is capable of acquiring, depend upon the degree of those attractions. Dufay had advanced thus far, but overlooked the importance of his one simple fact in the search for more recondite and complicated causes.

Mechanical
Processes.

The peculiar action of mordants remained still unexplained, except on the wild hypothesis of Hellot, till our Countryman, Mr. Keir, the ingenious translator of Macquer's *Chemical Dictionary*, suggested that, in dyeing, the earth of alum was precipitated, and in this form attached to the material prepared or dyed. Macquer soon afterwards adopted the opinions of Bergmann and Keir, and in the second edition of his *Dictionary*, under the article Dyeing, published in 1778, treated the subject in a more extended manner, and proved that these were the just conceptions of the nature and uses of alum, and of different metallic solutions as mordants in dyeing.

The successor of Macquer to the honourable appointment of superintending the dyeing establishments of France was Berthollet, a man of great scientific attainments. In a series of Memoirs inserted in the Transactions of the *Académie*, the *Annales de Chimie*, and *Journal de Physique*, he has examined various points of the Chemical theory of the Art of dyeing, and almost all his labours have been since directed to this object. In 1791 he published his *Elements of the Art of Dyeing*, in two vols. 8vo., a Work which has contributed more to the progress of the true theory and the general improvement of the Art than any other Treatise whatever. This Work has been translated into English by Dr. Hamilton, and a second edition of the original, with considerable additions, appeared in 1803.

In England, owing to the want of support of the Legislature of the Country, the Art of dyeing did not make so much progress as in France. We must not, however, forget to mention the labours of Dr. Henry, who communicated to the Literary and Philosophical Society of Manchester a Paper "On the Nature of Wool, Silk, and Cotton, as Objects of the Art of Dyeing, on the various Preparations and Mordants requisite for these different Substances, and on the Nature and Properties of Colouring Matter." This Paper is replete with new and ingenious views of the nature and objects, and of the principles of the combinations employed in the various processes. Dr. Henry first pointed out the peculiar nature of the aluminous mordant of the calico-printers; he showed that by double decomposition an acetate of alumina was formed, and explained its superiority over the sulphate of alumina, or the substitution of a volatile vegetable acid in lieu of the sulphuric.

Dr. Bancroft, in the year 1794, published his *Experimental Researches concerning the Philosophy of Permanent Colours, the best means of producing them by Dyeing, Calico-printing, &c.* This Work, as the title indicates, is rather an experimental than a practical Treatise; it contains, however, much valuable information, which the practical dyer may apply in many cases

Dr. Henry
Dr. Bancroft.

Manufac-
tures.

with considerable advantage, and it is also useful as containing a history of all the different substances of which it treats, and an account of the labours of Macquer, Dufay, Hellot, Berthollet, and others in this department of Science. Dr. Bancroft first pointed out the true action of tartar in the process for dyeing scarlet, and clearly proved that the nitro-muriate of tin, or any solution of tin alone, produced a crimson only, and that the addition of tartar produced a scarlet, by the conversion of a portion of the crimson colouring matter of the cochineal to a pure yellow. On this observation he founded an improvement in the scarlet dye, which consisted in communicating to the cloth, by means of quercitron bark, and any suitable mordant, such a shade of yellow as would produce, with the crimson of the cochineal, a pure scarlet. By the introduction of the quercitron bark Dr. Bancroft has rendered a most important and lasting service to dyers, as it is now become of so general and acknowledged utility as to supersede almost every other kind of yellow colouring matter whatever.

We must not conclude this account of those whose labours have advanced the Art of dyeing without mentioning the name of Dr. Ure, of Glasgow, to whom we are indebted for a translation of Berthollet's second edition of his Chemistry, with very useful illustrative notes and engravings, from which Work much of the information contained in the following section is derived. See also Packer's Dyer's Guide.

Theory of Dyeing.

(758.) Some Chemists have endeavoured to establish the phenomena of the change and variety of colours produced by the action of different substances upon each other, as witnessed in most of the operations of dyeing, upon the principles of colour laid down by Newton, viz., the decomposition of the rays of light by the absorption of a portion of its constituent colours and reflection of another. It does not appear, however, that Science can thus far be brought to the aid of this Art; but, as Berthollet very justly remarks:

Berthollet's
theory.

"Whatever may be the physical cause of colours, the colouring particles, which it is the object of the Art of dyeing to apply to stuffs, are known to possess Chemical properties, distinguishing them from other substances dependent on the affinities which their particles collectively exercise, as well as on the reciprocal action of these particles, and on their constitution, which disposes them, more or less, to assume the solid or the liquid state."

By virtue of these properties they dissolve in different liquids; they combine with acids, alkalis, oxides, with some earths, and especially alumina; they frequently precipitate the oxides and alumina from the acids which held them in solution; in other circumstances they even form super-compounds with the salts; sometimes they unite immediately to the stuffs; more frequently they form with these substances a combination much more intimate through an intermedium, or even they do not combine with it, except through the intermedium; the intermedium modifying their colour, their other properties, and even their composition.

Difference
of affinity
of colours

The difference in the affinity of the colouring particles for wool, silk, and cotton, is sometimes so great, that they refuse to combine with one of these sub-

stances, whilst they combine very well with another; thus, cotton takes no colour in the bath that dyes wool scarlet. Dufay got a piece of stuff made, the warp of which was wool, and the weft cotton; he passed this stuff through the fulling-mill, to ensure the same preparation to the wool and cotton; but the wool took the scarlet dye and the cotton remained white. It is this difference of affinity which makes it necessary to vary the preparations and the processes according to the nature of the substance which we wish to dye of a particular colour.

Mechanical
Processes.
for different
substances.

If the effects of the intermedia employed in dyeing, and the fixation of the colouring particles on a stuff by itself, or by means of an intermedium, be owing to the combinations which are formed, we must still refer to Chemical combination the changes produced by acids and alkalis in several vegetable colours, which Chemists employ for verifying the nature of different substances. We may compare the resulting compounds to neutral salts, which possess qualities distinct from those of their components, but in which one of the components may be in excess, so as to cause its properties to predominate. This state of combination is observed between the colouring particles of cochineal and the acidulous tartrate of potash, or cream of tartar. On evaporating slowly a solution of this salt in a decoction of cochineal, crystals are formed, which retain a fine ruby colour, much more intense and more lively than that of the liquid in which they were formed.

The reciprocal action of acids and alkalis being much greater than that which they exercise in particular on the colouring particles, they can mutually saturate each other, and then the resulting compound has little effect on the colouring particles; so that the changes which had been produced by one of the substances disappear, when it is neutralized by an antagonist substance.

Blue colours are not the only ones which can pass to red by the agency of acids, and to green by that of alkalis; most of the red colours, that of the rose, for example, are exalted by acids, and pass to green by alkalis; and some green colours, such as that of the decoction of burdock, and the green juice of the buckthorn berries, (*Rhamnus catharticus*), according to Becker, redden also with acids.

Action of
acids upon
colours.

This property, common to the most ordinary colours of vegetables, appears to prove that there is a close analogy between the greater part of their colouring matters; nor is it without foundation that Linnæus thought the red colour owing to an acid, of which he maintained the existence; but there are also several vegetables which contain a free acid, without possessing a red colour.

In the combination which the colouring molecules form with the stuff, they preserve only a part of their original properties; on being associated with alumina, with the oxides, and some other substances, they are somewhat modified; but the properties of the latter combinations are further modified when they unite with the stuff.

These modifications are analogous to what is observed in other Chemical combinations; but they are subject to a peculiar degradation from the action of air and light; sometimes, on the contrary, they receive from these agents a new lustre, or a different shade; there are also agents which, after combining with the colouring particles, alter the colour which they first produced,

Manufactures.

making it pass to yellow, and then destroy it; such, in particular, is oxygenated muriatic acid; it acts by means of the oxygen which it yields, and, consequently, differs in nothing except intensity from that of the atmospheric air.

It follows, from what has been stated, 1. That the colouring molecules have affinities which produce their solution and their combination, the effects of which, combining with those of their own constitution, form the differences that distinguish them from each other.

2. That they unite directly with the stuff, or by the aid of an intermedium; but the stuff has relations with them according to its nature.

3. That, in combining with a substance, they experience a change which modifies their colour, besides the modification resulting from the shade peculiar to the substance to which they combine.

4. That the colouring molecules differ not only from one another, by these different dispositions, but likewise by the ulterior changes which they may suffer from the action of other substances, and particularly from that of the air and light.

Of Mordants.

Mordants.

(759.) Of the numerous dyes with which we are acquainted, few can be applied to either animal or vegetable fibre, without some preparation beyond that of cleansing the stuff and immersing it in the dyeing-liquor. When colours can be fixed upon cloth without any previous preparation, they are called *substantive colours*. When they cannot be so fixed, but require the interposition of a third substance, they are called *adjective colours*, and the substances interposed are called *mordants*. Sometimes substances are employed merely with the view of changing the shade of colours, whose action is different to that of mordants. These are termed by Berthollet *alteratives*.

Mordants merit the greatest attention. It is by them chiefly that we diversify the colours, give them more brilliancy, fix them on the stuffs, and render them more durable. A mordant is not always a simple agent, but in the mixture composing it different combinations are sometimes formed, so that the substances which have been employed do not act immediately, but by the resulting combinations. Sometimes the mordant is mingled with the colouring particles; sometimes the stuff is impregnated with it before being exposed to the dyeing-bath. On other occasions these two methods are combined. We may dye in succession with liquors which contain different substances, the last of which acts only on the parts with which the stuff has been imbued by the preceding operation. One solution, which is to yield its basis to the stuff, has need of heat; another requires the operation to be made in the cold. The mordant is frequently an oxide; in which case its properties may vary, not only according to its actual condition, but also according to the action of the substances with which it is associated, and even according to the circumstances of the operation. It is by the determination of all these conditions that Chemistry can particularly direct the Art of dyeing, can establish its processes in a constant manner, removing from it whatever is useless or prejudicial, and transferring to one kind of dyeing what is found efficacious in another.

The substances employed as mordants should, therefore, furnish a base which attaches itself to the stuffs and to the colouring particles, and which resists their

re-dissolution and destruction. As to those substances, however, which occasion merely some modifications in the colours, it is sufficient for them to be retained in small quantity in the combination formed between the stuffs, the mordant, and the colouring matter. Hence, although alteratives act equally by combining, they should be distinguished from mordants, which serve to fix the combination.

Acids can, in general, dissolve the colouring substances, but as they do not themselves possess the property of combining with the stuff, they cannot serve as bonds of union; on the contrary, they usually carry off the colouring particles which had been retained by the stuff, and they contribute to the colour which is fixed, only in the quality of alteratives, by uniting in small quantity to the coloured combination.

Potash, soda, and ammonia, cannot serve as intermedia to fix the colouring substances on stuffs; but they may, as well as acids, effect the solution of colouring substances on which they have an action. Their affinity with the stuffs should also tend to co-operate their solution. It is only as alteratives that these alkalis can enter into coloured combinations. If they produce some precipitation in the watering solutions of colouring substances, it must be merely by separating a body much more soluble from another in itself slightly soluble, or by occasioning some change in a substance of somewhat unstable composition. The other alkalis, namely, lime, barytes, strontites, and magnesia, which possess little solubility, or a much greater tendency to solidity, appear fitter to serve as mordants. In fact, these alkaline earths have sufficient affinity to form, with colouring substances, combinations which are precipitated from their solution; but they considerably affect their colours by their alkaline properties. They possess too weak an affinity to enter into an insoluble combination with the stuffs; so that, far from promoting the union of the colouring particles, on the contrary they obstruct it, forming insulated precipitations.

The body which possesses in an eminent degree the properties suitable for a mordant is alumina. Insoluble when it does not experience the action of acids or alkalis, it has a strong disposition to combine with the colouring particles; it does not act on their colours as the alkalis do, but it preserves very nearly their natural hue. It separates also much more easily from the acids which hold it in solution than the alkaline bases do.

Metallic oxides possess such an affinity with several colouring particles, that they abandon the acids which kept them in solution, to precipitate in combination with the colour. On the other hand, all the oxides possess the property of combining with animal substances; which several combinations may be formed by mixing with the metallic solutions an alkali saturated with the animal substance.

The oxide of tin surpasses all the others in its property of becoming fixed on woollen and silken stuffs, but especially on the former. It readily abandons the acid which holds it in solution to combine with them, so that it is sufficient to impregnate wool and silk with solution of tin, although they should be then thoroughly washed; a process which does not answer with other metallic solutions.

Tin slightly oxidized has, in reality, only an ashy colour. But since it has a great affinity for oxygen, it takes enough of it in the ordinary solutions to pass to the white colour; or it may complete its oxidizement,

Mechanical Processes.

Action of acids as mordants.

Alkalis.

Alumina.

Metallic oxides.

Oxide of tin.

Manufactures.

Oxide of zinc.

even during the operations of dyeing. It retains its oxygen with force, and hence, when highly oxidized, its oxygen exerts but little action on a colouring matter. The oxide of zinc appears to possess analogous properties, but it has much less affinity with stuffs and with colouring particles, while, on the other hand, it retains the acids more powerfully, and is thereby much less fit for a mordant.

The affinity of the oxides for substances of a vegetable nature appears to be much weaker than for animal substances, whence it happens that metallic solutions are not well adapted to serve as mordants for colours in cotton and linen. An exception must, however, be made in favour of the oxide of iron, which may be applied in a very solid manner to these substances, even when it is precipitated from its solutions. To this purpose Chaptal makes an interesting observation. He states that a solution of iron disturbed by precipitation may be cleared up by moving cotton and linen through it. We must, however, observe that the oxide of iron differs in colour according to its state of oxidation; and that the action which it exercises on the colouring substance varies, as we shall see, according to that state. The oxide of copper has also some affinity for linen and cotton, so that its solutions may be employed in some processes, and oxide of manganese possesses a similar property.

It follows from what has been stated, 1. That the acids and the alkalis are not fit for mordants, that is to say, for intermedia or bonds of union between the stuffs and the colouring substances, although those of sparing solubility can produce species of lakes with colouring matters. 2. That of all the earthy substances, alumina is the one eminently endowed with the properties of a mordant, from its affinity with colouring substances and with stuffs, and from its feeble attraction to acids. 3. That among metallic substances we must distinguish those that afford a white base to the colouring substances, and those which affect the colouring matters by their own colours. Among the former, which are fit for light and splendid colours, the solutions of tin hold the first rank, from the affinity of its oxide for the stuffs of an animal nature, and for the colouring substances, as also from its weak attachment to acids. The force with which it retains oxygen contributes to its qualities. Among metallic substances, whose colour produces modifications, iron is of the most extensive employment, but its effects vary according to its state of oxidation.

When the colouring particles have precipitated an oxide from its solvent, the latter has usually the power of dissolving a portion of the combination of the colouring substance with the oxide, and the liquid remains coloured, although the precipitation may be facilitated and rendered more complete by the presence of the stuff. The effects depend, therefore, in part, not only on the proportion, but also on the species of acid which acts as a solvent to the oxide. This observation is applicable to acids which hold alumina in solution; but the acids, alkalis, metallic solutions, and even the neutral salts, may serve as alterants.

By varying mordants we greatly multiply the shades attainable by one substance, especially with the co-operation of alterants. The same effect may also be produced by the method of applying mordants. Thus we obtain different effects by impregnating a stuff with a mordant, or by mixing the mordant in a dyeing bath, by making the operation with heat or cold, with the continued

contact of air, or without its intervention, by means of a solution in a strong acid, or of one in a feebler or more volatile acid. Mechanical Processes.

Dyeing favours the combination of the bases which have an affinity for the stuff, because the water which produces the solution resists, by its own affinity, the action of the stuff that tends to bring it into a solid state. But the circumstances by which we ought to be regulated vary according to the qualities of the stuff, which, by a disposition whose cause cannot be assigned, requires sometimes the aid of heat, whilst a stuff of a different nature combines better in the cold. Finally, the processes which a stuff should receive in succession, to attain the proposed end, sometimes decide the choice of the solution of the mordant and the manner of applying it. This is particularly observable in reference to cloths for calico-printing, which should be able to pass through several operations without receiving injury from any of them.

Astringents.

(760.) We have now to speak of another class of agents which are very important in obtaining some colours, particularly black. The name of astringents is applied to those substances which have the property of giving to iron the power of decomposing water, and forming by this means a solution of iron, which passes from blue or violet to black. The most important substances of this class are

Nut galls.
Oak bark.
Logwood.
Sumach.

On mixing a solution of iron with an infusion of any of these substances, the mixture becomes black, and will give to silks and stuffs the deepest and most indelible black colour.

The shade of black produced by these different substances varies, however, a good deal, which has led many to consider the astringent property not owing to an individual principle. Dr. Bancroft is of that opinion; and he remarks, on this subject, in his very excellent Treatise on colours, "I have invariably applied the name of astringent to those parts of vegetable dyeing drugs which are found to produce colour with an earthy or metallic base, and I have never been able to discover any good reason for doing otherwise in regard to those vegetable matters which afford ink or black dye with iron,—matters indeed which are extremely various in their other properties, and even in the sorts of black which they produce; though Chemists have, I think, improperly confounded most of them under the general denomination of astringents,—a term which may be unobjectionable, as signifying acerbity in vegetables, but not as indicating or being invariably connected with any such property of matter as they have been even supposed to possess, that of producing black colour with iron." Dr. Bancroft's theory.

Berthollet was of a decidedly different opinion, as may be learnt from the following remarks: "If gallic acid, the different species of turmeric, and several other colouring substances, such as logwood, Brazil wood, and madder, afford, with solutions of iron, blacks more or less deep, there must be something in common in the mode of acting of these substances, whatever may be in other respects the difference of their properties."

Berthollet, together with Lavoisier, Vandermonde,

Effects by varying mordants.

Manufac-
tures.Experi-
ments of
Berthollet,
Lavoisier,
&c.

and Fourcroy, was directed by the French Academy to make experiments on the different astringents, and to report on the subject. The substances upon which they instituted the experiments of comparison were galls, oak bark, rasping of heart of oak, the external part of oak, logwood, and sumach. They estimated the quantity of the astringent principle by the quantity of sulphate of iron which a solution of each would decompose, and afterwards by the weight of the black precipitate which was formed.

The results were as follows :

	drs.	grs.
Decoction of two ounces of galls required to saturate it	3	61
Weight of the precipitate	7	24
Ditto of oak bark	0	18
Weight of the precipitate	0	22
Ditto of heart of oak	1	24
Weight of the precipitate	1	24
Ditto of logwood	1	48
Weight of the precipitate	2	12
Ditto of sumach	2	18
Weight of precipitate was not ascertained.		

These eminent Chemists concluded, from the results of their investigation, that the quantity of astringent substances required to give a black colour of equal intensity, to an equal weight of the same cloth, were proportional to the quantities of astringent principle which had been estimated in each kind by the foregoing experiments ; but that the black obtained by the different parts of oak did not resist tests or proofs as well as that produced by galls. It appears also that logwood alone was incapable of producing so intense a black as galls or oak, nor was the colour so permanent.

It is found that the mixture of two of these substances yields a more intense black than when one is used singly. Thus, in practice, a decoction of logwood is added to that of the galls. It is also advantageous to fix a blue colour on stuff which is to be dyed black.

Other uses
of astrin-
gents.

The use of astringents is not confined to dyeing black colours ; they exert on several colouring particles an affinity which serves to fix them on stuffs, and to communicate stability to them. In this point of view they may be compared to mordants ; but as they possess in themselves a colour which has a tinge of yellow or dun, and as the effect of one colour must be to modify and darken that peculiar to another colouring substance, the use of astringents as mordants does not suit bright colours, particularly those of little intensity.

Substances used in Dyeing.

(761.) These substances may be divided into two principal classes, viz., the vegetable and mineral, to which are to be added, however, some of animal origin and various chemical compounds. In the following arrangement,—in consequence of the difficulty in some cases of drawing a line of distinction between the classes, or rather of deciding upon the class to which some particular substances should be appropriated,—we have included those of animal origin in the first division, and the chemical compounds, which are generally mineral, in the second. The substances are arranged alphabetically in each division, with the purpose for which they are employed, the substances from which obtained, and any other information on the subject of each which appeared of importance

(762.) Vegetable and Animal Colours used in Dyeing.

Mechanical
Processes.Various
dyeing sub-
stances.

Annatto is employed in dyeing silk and cotton yellow: it is produced from a reddish pulp which covers the seeds of the *Pixa orellana*, a plant which grows spontaneously in different parts of Guiana. This substance is in more common use on the Continent than in this Country.

Archil is generally employed by dyers to give bloom to other colours ; it is obtained from a whitish lichen which grows upon rocks in the Canary and Cape de Verd Islands ; it yields a rich purple tincture, extremely beautiful.

Argol, tartar, or *supertartrate of potash*, is employed in producing scarlet and some other colours, and for various purposes in dyeing. It is a crystalline substance deposited in wine-casks during the fermentation of the wine from the juice of the grape, in which it exists in considerable abundance. Cream of tartar is the same substance, freed from the colouring and other extraneous matter.

Barwood is employed with the aluminous mordant in giving a yellowish brown red to wool and cotton. The colour is, however, rather fugitive on the latter. It is obtained principally from Angola, in Africa.

Blood, generally that of sheep, is employed in dyeing Adrianople red, and some other colours.

Bran is employed to loosen and remove colouring matter, and, in some cases, to alter its hue.

Brazil wood is employed for dyeing red colours. It is obtained from the heart of a tree, which Linnæus describes under the name of *Cæsalpinia crista*, and is a native of Brazil, from which it derives its name.

Cæsalpinia sappan is employed for the same purposes as Brazil wood, to which it is nearly allied in properties.

Cam wood is also employed in dyeing red. It is obtained from a tree imported from Africa by the Portuguese. *Jamaica brazilleto* and *Bahama brazilleto* probably belong to the same species, although they are usually classed as different. They afford the least valuable of the dyeing woods, and are only employed in producing inferior and fugitive colours.

Cochineal is employed for dyeing various shades of red : it is obtained from the female insect of the *Coccus cacti*, found on the *Cactus coccinellifer* and *Cactus opuntia*, natives of South America, the West Indies, and other tropical regions. This is one of the most important colours used by dyers.

Cudbear is employed for dyeing various shades from pink and crimson to Mazarine blue. It is manufactured in this Country from archil.

Galls are employed in dyeing as astringents. They are excrescences produced on the *Quercus infectoria*, a species of oak growing throughout Asia Minor, but chiefly exported from Aleppo. The gall grows on the shoots of the young boughs, and is produced by an insect, the *Cynips quercusfolii*, which punctures the young shoot with its sting, and deposits its egg in the puncture. The egg is soon hatched, and the irritation of the maggot feeding on the plant produces the wen or gall-nut.

The gall or bile of animals is employed by some dyers and scourers in preference to soap for cleansing clothes. It is a bitter yellowish fluid, secreted by the liver, and found in the sac usually called the gall-bladder.

Gums, Senegal, Copal, &c., used chiefly in calico-printing.

Manufac-
tures.

Indigo is employed very largely in dyeing blue colours. It is obtained from a plant, the *Indigofera tinctoria*, or Indigo-bearing plant, a native of the East Indies, and is exported here both from the East and West Indies, and America. (See Indigo Works.)

Kermes is employed in dyeing scarlet. The use of this dye has been almost entirely abandoned in Europe since the introduction of cochineal. It is produced from an insect (*Coccus ilicis*) found in several parts of Asia and in the South of Europe.

Lac is employed for dyeing red and scarlet. It is of animal origin, being produced by the *Coccus lacca*, a small winged insect, and is generally deposited on the small branches of the *Croton lacciferum*, a tree which grows in India. As an article of commerce lac is known in Europe under the appellations of stick lac, seed lac, and shell lac. The first is the lac in its native state, as it is found adhering to the twigs. The seed lac is a yellowish hard resinous substance, which remains after the red colour of the stick lac has been extracted; and the shell lac is produced from the seed lac by putting it into long bags of cotton cloth, melting it over a charcoal fire, and straining it through a cloth.

Logwood.—The principal consumption of this substance is for dyeing black and various shades of greys. It is also employed very extensively for different compound colours, and there is, in fact, no colouring matter with which we are acquainted capable of affording so great a variety of dyes, although this advantage is much diminished by the want of permanency. This substance is the wood of an Indian tree (*Hæmatoxylon Campechi-anum*.) For the method of preparing it for the dyer, see article Colour-mill.

Madder.—Also a very important colour in dyeing, employed to give a red colour. It is the root of a plant which Linnæus divides into two species, the *Rubia tinctorium foliis senis*, and the *Rubia peregrina foliis quaternis*, and is exported into this Country from Zealand.

Peachwood is employed in giving a maroon colour. It is obtained from a tree resembling the Brazil wood, but does not yield above one-third of the colouring matter.

Quercitron or *American bark* is employed for dyeing yellow, and was brought into notice by Dr. Bancroft, who obtained the exclusive privilege of using it as a dye, by an Act of Parliament passed in the 25th year of the reign of George III. It is obtained from the *Quercus nigra*, or black oak, a native of North America.

Safflower, *Bastard Saffron*, or *Carthamus*.—This dyeing material consists of two colouring substances, a yellow and a red. The former is of little value; the latter, which is soluble in alkalis, forms, by preparation with acids, a beautiful red pigment, sometimes used for silk-dyeing, but more commonly in the preparation of rouge. It is obtained from one or two plants, species of the *Carthamus* genus, natives of the south of Europe and the coasts of the Mediterranean.

Sumach is employed alone to give a brown and a fawn colour. Cotton stuffs, impregnated with acetate of alumina, take a durable yellow from it. It is the production of the *Rhus coriaria*, a shrub which grows in Syria, Palestine, Spain, and Portugal.

Turmeric is employed chiefly for dyeing yellow. It is of a very rich colour, and said to surpass every other yellow colouring matter in beauty. It is, however, in consequence of its slight affinity for stuffs, or the mordants which are usually employed, not by any means perma-

nent. It is obtained from the root of the *Curmuna*, a Mechanical Processes. plant growing both in the East and West Indies.

Weld.—Also employed to give a yellow colour. It is obtained from a plant (*Reseda luteola*) which grows wild in this Country, but is cultivated for the purposes of the dyer.

Woad or *Pastel* is employed to give a blue colour. It is obtained from a plant (*Isatis tinctoria*) growing in various parts of Europe and in this Country, and is cultivated with great care for the dyeing matter which it affords, and which is obtained from the leaves of the plant, collected and prepared in a particular manner. See article Colour-mill.

In addition to the above vegetable colours may be mentioned Dyer's broom, Sawwort, French berries for yellow colours; Walnut root and the outside green shell of the nuts for brown; and *Chay* and *Galium* for red. These substances are not, however, employed to any extent.

(763.) Mineral and Chemical Substances used in Dyeing.

Alumina, Sulphate of, or *alum*, is employed by calico-printers and dyers as a mordant; 100 parts are composed of sulphate of alumina 36.70, sulphate of potash 18.88, and water 44.42. It is found native in some places, but the greatest part of the alum of commerce is prepared from the schistose pyritic clays usually denominated alum ores. Alum is made at Civita Vecchia, in Italy, and also at many other places on the Continent; at Hurlett, near Glasgow, at Whitby, in Yorkshire, &c. See Alum-works.

Alumina, Acetate of, is employed in large quantities by calico-printers in the preparation of mordants.

Arsenic, Sulphurets of.—Orpiment and realgar have been applied to the purposes of dyeing a yellow colour. The sulphur is combined with these two minerals in different proportions. Realgar is of a red colour: it occurs native in Germany and Switzerland; it is also produced by art. Orpiment is produced by art, and is of a yellowish colour. Native orpiment is also occasionally found. It is of a bright lemon-colour.

Arsenic, Oxides of, are also used in dyeing, as mordants.

Copper, Acetate of, or *verdigrise*, is employed as a green colour. It is obtained by exposing copper plates to the husks of grapes, which contain a great quantity of acetic acid; the sulphate of copper, or blue copperas, the nitrate, and prussiate also, are employed in dyeing. Dr. Bancroft proposed to employ the oxides of copper as substantive colours, but they do not appear to have been adopted.

Iron, Acetate of, is much employed by calico-printers as a mordant, and in combination with other colours. The sulphate of iron, or green copperas, the muriate and prussiate also, are employed for various purposes in dyeing. The latter salt is the beautiful pigment termed Prussian-blue.

Iron, Oxides of, are employed very extensively as mordants, and constitute the basis of all black colours.

Lead, Oxides of, are used as mordants, but they are said to tarnish the lustre of the colours. The *acetate* and *sugar of lead* also are employed for various purposes by the dyer.

Mercury, Muriate of, or *corrosive sublimate*, is employed as a mordant.

Muriatic acid is employed as a solvent for some colours.

Manufac-
tures.

Nitric and *nitro-muriatic acid*, or *Aqua regia*, sulphuric, and some other acids are employed for the same purpose.

Oxymuriatic acid, or *chlorine*, whose valuable services in bleaching have been already described, is employed in dyeing as a test for the durability of colour.

Potash, *pearlash*, and *soda* are employed for various purposes in dyeing.

Tin, *Nitrate of*, is employed very extensively as a mordant. The solution of tin commonly used by dyers, termed spirit, is prepared with very dilute nitric acid, which dissolves about one-eighth of its weight of tin, previously reduced to a granulated form. The *muriate*, the *nitro-muriate*, the *murio-sulphate*, and other salts of tin, are also used very effectively as mordants.

We might enumerate many other substances used by dyers, but as the use of them is neither frequent nor important, and can be supplied by some of the substances above named, we conceive it unnecessary to lengthen our columns by the addition of them.

On the different Branches of Dyeing.

Subdivi-
sions in the
process of
dyeing.

(764.) In the Art of dyeing, as in most other processes, an advantage is derived from carrying on the works on a large scale, not only from the general principle that by the subdivision of labour, each workman, occupied with a single object, acquires celerity and perfection in his employment, but because the residuum of one process can be applied very frequently with advantage in another. From the immense extent of the Art in this Country, this principle must be adopted, and certain subdivisions into different branches had recourse to. Thus we have woollen dyers, who are occupied solely in colours obtained from cochineal, such as scarlet, crimson, orange, buff, &c., and others in dyeing purple, or royal purple: they are called grain-dyers, from the circumstance of the colouring material, cochineal, being in small grains. It ought, however, to be observed, that the term dyed in grain is applied by the public generally in a very different sense, namely, to those cloths, the raw material of which is dyed previously to being spun into thread, or at least before it is woven into cloth; and hence such dyes are usually more permanent than those which are dyed after the materials are woven into cloth. Grain dyers generally dye cloth in the piece, or in a number of pieces tacked together, and worked over a winch in a suitable copper.

There are dyers likewise who dye worsted and woollen yarn of those grain-colours, which is generally a distinct branch. The yarn is dyed in hanks upon sticks, and when in the copper, the hanks are changed end for end, so that they may be kept even, such changing being performed five or six times to each turning. There are also silk-dyers who are grain-dyers, who dye in the skein chiefly for new goods. Some silk and some mixed silk and worsted goods are dyed in the piece.

Dyeing cotton of the Adrianople, or Turkey-red, is in many cases a branch of itself, and comes nearest to what may be called grain or scarlet-dyeing upon cotton, because cochineal cannot be applied with any advantage to cotton. Cotton is, however, occasionally dyed with that material.

In dyeing woollen manufactures, another branch consists of woad-dyers, which very commonly includes the black dye on woollen cloth, as well as the blue from woad and indigo. There is the same distinction among

worsted-yarn dyers they have likewise to do slates, greys, &c. Nearly the same may be said of the silk-skein dyers. In many places, browns, drabs, stone-colours, &c., constitute a branch in woollen-dyeing. The same colours also form a branch in calico and muslin: but black in calico and muslin is a distinct branch.

The following constitute also particular branches, black hats, hats of fancy colours; fur; chip and straw; feathers; leather, Morocco and Spanish, and kid for shoes and gloves. Some other branches might be enumerated, but more detail does not seem necessary.

On the Arrangement of Dye-houses and the Apparatus employed.

(765.) A dye-house ought to be spacious, well lighted, and as near as possible to a stream of water. It should be floored with lime and cement, and provided with ready outlets for the water and spent-baths, and the whole so ordered as to ensure the utmost cleanness.

The arrangement and size of the boilers must depend on the operations for which they are intended; they should be made of copper or brass, except for dyeing scarlet, for which purpose it is better to employ boilers of tin, as well as for other delicate colours, where a solution of tin is made use of. Brass is less liable to be attacked by saline substances, and to stain the goods, than copper. In many cases, vessels of wood may be substituted for metal boilers. It is of consequence to cleanse the boilers well after each operation, and such as are of great capacity ought to have in their bottom a copper pipe with a stop-cock at its outer end, which is opened when the baths are to be emptied. Above each boiler, holes are pierced in the chimney-piece, or wall, for resting the ends of the poles, which serve to sustain the hanks of wool or silk while draining, or any stuffs, of which only small portions are to be dyed, by means of which the bath-liquor falls back again into the boiler. For piece-goods a winch or reel is employed, the two ends of which rest on two forks of iron, placed at pleasure in holes bored in the curl which supports the edges of the copper.

Several silk and cotton dyes, for which ebullition ought not to be employed, are performed in long vessels of copper or wood, called troughs or backs.

As the most part of colours applied on silk are very delicate, they require to be speedily dried, to prevent their changing. For this purpose a drying-room is provided, which is heated by means of a stove. The silk is stretched on a moveable pole called a shaker, which is hung up and agitated to accelerate desiccation. A drying-room is also used for cotton cloths which have been impregnated with a mordant. Cylinders heated by steam are now very frequently employed for drying.

When one or more pieces of goods are to be dyed the winch-reel is employed. One end of the cloth is wrapped round the reel, which being turned quickly carries round the whole piece in succession. It is then turned in the opposite direction, in order that that part of the reel which was first plunged the former time may be last at the second immersion, whereby the dyeing is rendered as equable as possible. If the pieces of goods be long enough, or if several are to be dyed of the same colour, their two extremities are stitched together, the winch is passed within, and then set on its forks.

When wool in the fleece is to be dyed there is set

Wool-
dyeing.

Manufac-
tures.

over the boiler a frame-work of wood resembling a ladder with the bars placed very close together. On this the wool is laid to be drained and aired, as well as during the changing of the bath.

After silks and yarns have been dyed, it is necessary to wring them, in order to squeeze out the excess of colouring matter. This operation is performed on a cylindrical piece of wood, which is fixed at one end in a wall or to a post.

Colour-
mills.

Dye-houses very commonly contain Machinery for preparing the colours, which consist of various descriptions of mills for the purpose of reducing the ingredients into minute portions, in order that the colouring matter may be readily extracted from it. These have been already described under Colour-mill, to which we refer the reader.

On the Preparation of the Colours.

(766.) Dyeing is one of the Arts in which Machinery performs a very unimportant part in the processes; the department in which the attention and skill of the dyer is most profitably employed being that of the mixture and proportion of the different ingredients. The immense number and variety of colours, all of which require an operation peculiar to themselves, however, preclude the possibility of entering here upon this subject at a length that will be serviceable to the practical dyer. We trust, however, that the following remarks upon the composition of the principal colours may not be without interest and service to the general reader.

On Dyeing Black.

Dyeing
black.

(767.) Very few substances are known which can of themselves afford a solid black, and they have been tried only on linen and cotton. The juice of the cashew nut, or *anacardium* of India, communicates a black colour which resists even boiling with soap and alkaline leys.

The *Anacardium occidentale*, and some other shrubs, yield a dye which is nearly black, but they can be procured only in such small quantities that they are scarcely at all employed in English dye-houses, all blacks being produced by the action of astringents upon iron.

Dyeing silk
black.

A very common process for dyeing silk black in our dye-houses is to boil together, for three hours, $1\frac{1}{2}$ bushels of alder bark, 14 pounds of logwood, and 1 pound of iron filings, at the end of which time the fire must be damped. Four ounces of sulphate of copper in water are then added to the liquor, and well mixed. The silk is immersed four times in the liquor, and aired on the floor until it is cold between each time; three pounds of sulphate of iron are then added to the copper, and two more immersions given to the silk.

The drugs are left to boil as much as they will during the night, and, the next morning, the silk is again immersed four or five times, and left in the copper all the following night, the liquid being at a temperature considerably under the boiling point.

Dyeing
cotton
black.

In dyeing cottons black the goods are commonly passed through a blotching Machine to receive a mordant of acetate of iron, and galled slightly, but Sumach is used instead when galls are dear. The cotton is then passed through a bath of logwood, or of logwood and fustic, and then through sumach. They are again galled, and the same processes repeated until a full and rich black is produced.

In Manchester the dyers make a black iron liquor by

filling casks with layers of old hoop iron rusted in the air and cut into small pieces, with intermediate ones of alder bark. The casks are filled with water and left for six weeks or two months. This liquor is used after goods have been passed several times through a decoction of logwood and sumach, and through sulphate of iron. It is said that the black produced by this means is much esteemed for all cotton goods.

Mechanical
Processes.

Cotton and silk are sometimes dyed with a blue ground, but it is not found to enrich the black as in dyeing wool, where a good black cannot be attained without it.

Indigo for the ground is the richest and most common drug. A great many articles, however, have a ground of logwood, or logwood and alder bark, or of logwood and old fustic, or all these substances boiled together. Logwood has a tendency to give the black a foxy hue, which the alder bark and old fustic correct, but they must be used in small quantities for this purpose, because the dye from these will produce a soot or dead black.

Blue
ground for
dyeing
wool.

After the blue ground is thus given, the black is commonly produced by sumach, sulphate of iron, and a small quantity of verdigrise. Some dyers boil the stuffs in alum and tartar; in fact, almost every dyer has a black of his own produced by a different process, so that it is impossible to describe any decided mode of producing this colour on wool.

Of Grey Colours.

(768.) The greys being shades of black, their colours are produced by the same substances. In dyeing silk, a bath is prepared with fustic, logwood, archil, and sulphate of iron, which ingredients are varied according to the shade to be given. Thus, more archil is employed for greys that are to have a reddish cast, more fustic for those which ought to incline to a russet or green, and more logwood for such as are to have a darker grey. For the iron grey, logwood and solution of iron are had recourse to. The black grey requires the addition of a solution of alum, after which the silks are taken to the river, and then receive a bath of weld. A portion of this bath is thrown away to substitute for it the extract of logwood. When the silk has been impregnated with this, solution of iron is added in sufficient quantity, and when the desired shade is attained, the silk is washed and wrung.

Dyeing
silks grey.

Should the grey come out deeper than is desired, the silk is turned through a solution of tartar, and then through hot water, and if the colour be too much weakened a fresh dye bath is given it.

For linen and cotton, a blue ground is given to black grey, iron grey, and slate grey, but not to the other greys. All the shades require a galling proportioned to the grey which is wished to be procured. Baths of nut galls that have been previously used are often employed.

Dyeing
linen and
cotton grey

When the yarn has been galled, wrung, and dried, it is turned over sticks in a bucket full of cold water, to which a quantity of a black iron liquor with logwood is added. The yarns are worked in it in separate portions; then hung out and dried.

Another very good process consists in taking a quantity of very dilute acetate of iron, and a decoction of sumach, also very dilute. The cotton is passed in succession from one liquor to the other, till the wished-for shade is attained. The finish is given by passing the goods through water slightly acidulated with sulphuric

Manufac-
tures.

acid, otherwise the sumach gives a russet hue. By the same process with nut galls, less lively greys are attained, and the alder bark affords an agreeable one which borders on hazel.

Dyeing
wool grey.

For dyeing wool a decoction of pounded nut galls is prepared, and the sulphate of iron is separately dissolved. A bath is made corresponding to the quantity of stuff which is to be dyed, and when it is as hot as the hand can bear, the decoction of nut galls and solution of sulphate are poured into it. The wool is then immersed, and, if in withdrawing it is not found to be of a sufficiently dark shade, more of the solution and decoction are added, and thus any shade of a brown grey can be attained by adding more of the two liquors. It is, however, better for the black grey and the other deep shades to give a blue ground previously to the stuff.

The greys are very useful colours in dyeing, not only from the prevalence of the colour, but from their application to other colours which operation is called saddening or darkening.

Of Blue Colours.

(769.) The preparation for dyeing blue is not generally made in boilers as for most other colours, but in large wooden vessels termed vats, which are very commonly heated by steam, in order that a regular heat may be maintained.

Dyeing silk
blue.

Blue may be dyed with pastel or woad, but it is by no means so rich in colour as with the addition of indigo. In dyeing silk, woad is not employed, the indigo being the only colour. In preparing it, a quantity of alkaline ashes, bran, and a small quantity of madder are boiled together, which are poured into a vat containing the indigo, and all well mixed by raking. The vat must now be heated, closed, and left for about forty-eight hours, when it will, if properly managed, appear of a fine green, covered with coppery flakes and scum; the goods may now be immersed in it until the desired shade is attained.

The ashes are a solvent to the indigo, and cause by their action a more intimate mixture with the water. The use of a substance as a mordant is not required in dyeing this colour, indigo being one of the substantive colours, or rather it has a natural Chemical affinity to the silk.

In giving a deep blue to silk it is necessary to prepare it by giving it another colour as a ground, which is commonly done by a bath in archil. A blue is sometimes given to silk by means of verdigrise and logwood, but it is by no means a durable colour.

Saxon blue.

Saxon blue, so named from being discovered in Saxony, is produced from a dye composed of indigo and sulphuric acid. In making this dye Bergmann uses one part of indigo well pulverized with eight parts of sulphuric acid so concentrated that its specific gravity is to that of distilled water as 1.90 to 1.00. After twenty-four hours the indigo will be dissolved, producing a mixture perfectly black and opaque, which, by diluting with water, is fit for use. For cotton it is, however, necessary to neutralize the acid by some alkali, which is generally done by pearl ashes and lime.

Dyeing
cotton and
wool blue.

In dyeing cotton and wool a blue vat is commonly prepared of woad and indigo, by first boiling in about a gallon of water 2 ounces of potash, $\frac{3}{4}$ of an ounce of madder, and 1 ounce of bran. After it is sufficiently boiled and well settled, it is put into another copper with 4 ounces of indigo finely powdered; the liquor should be kept stirred and very hot, but not be allowed to boil.

At intervals, some lixivium of lime should be put into it, and that being cold will keep the liquor from boiling, and render the potash more active. As soon as the indigo is dissolved and properly diluted, the fire is damped and the solution covered over. In preparing the woad-mixture about 5 pounds of woad are mixed in 12 gallons of water with 1 ounce of madder and about a handful of bran, kept at about a blood-heat, and stirred for 12 or 14 hours, when the indigo prepared as above described is added to it, and the goods are immersed; the quantity of indigo which must be put into the vat being determined by the shade which the goods are required to possess. Lime is generally added to the woad-vat, but care must be taken that an excess is not made use of, or the colour of the vat will be spoiled, yielding to any substance put into it a dirty grey instead of a blue.

A very beautiful blue may be given to all kinds of goods by Prussian blue, but some difficulties have been experienced in rendering this colour permanent. In using it, it is commonly dissolved in muriatic acid, and diluted. As the Prussian blue cannot be perfectly dissolved, but only attenuated, it falls down rapidly on the stuff, and very often causes the colour to be wavy. To avoid this, the stuffs must be passed very rapidly through the solution, and the operation repeated very frequently.

A combination can be produced between the prussiate of iron and a stuff only when the oxide of iron is previously combined with the stuff so as to receive the prussic acid; but on impregnating a stuff directly with a solution of iron, in order to combine it with the oxide of this metal, inequalities are inevitable, which become very obvious when they are changed into prussiate. This inconvenience is avoided by dyeing the stuff first grey, or a deeper shade, according to the blue wished to be obtained, for in this primary dye a more uniform combination is made of oxide of iron and of astringent matter with the stuff.

The French Government, in 1801, granted to M. Raymond the sum of 8000 francs, as a reward for communicating to the Public his process for dyeing of a uniform fast and bright Prussian-blue colour. His process is as follows: He first converts, by gentle calcination, sulphate of iron into a red sulphate of iron, which he dissolves into sixteen times its weight of water, and filters. The silk, prepared as for indigo dye, is put into the solution of iron, and left there more or less time, according to the shade of blue which is wanted; it is then taken out and wrung very dry on a pole placed over the vat. It is then thoroughly cleansed by being twice bathed, plunging and agitated each time, in running water.

Dissolve in pure water heated to 167° one ounce of ferro-prussiate of potash for every twelve ounces of silk to be dyed, and when the prussiate is dissolved, add one part or even rather more of muriatic acid, stirring the mixture well. When the liquor has acquired a greenish colour, the silk must be plunged into it and stirred about for some minutes until it has received sufficient colour; it must then be well bathed and washed, in order to free it from any portion of the prussiate of iron not truly combined with it.

The silk must lastly be agitated in a vessel of water, with two pounds of water of ammonia with it, for every 100 pounds of silk, by which process the blue becomes many shades deeper and of a much richer and brighter tint, and, at the same time, is fixed more perfectly in the silks.

Manufac-
tures.

Of Yellow Colours.

(770.) In dyeing all yellows it is necessary to employ mordants, because the affinity of yellow colouring matters for either animal or vegetable stuffs is not sufficiently strong to produce durable colours. Yellow colours, therefore, belong to that class which Dr. Bancroft has denominated Adjective Colours.

Dyeing silk
yellow.

The substances capable of giving a yellow colour to different stuffs are very numerous, but those most commonly employed are weld, fustic, annatto, and quercitron bark. For silk no other ingredient is generally used except weld. The silk must be first well scoured, alumed, and washed. A bath is made with two parts of weld for one of silk, and after one hour's ebullition it is filtered through a cloth or sieve into a vat, and when sufficiently cool to allow the hand to be plunged into it, the silk is immersed, during which operation the weld is boiling a second time in fresh water. One half of the first bath is now thrown away, and the deficiency made up by the decoction of weld from the fresh bath, and the silk again immersed. A quantity of crude pearl-ash is dissolved in a portion of the second decoction, which is added to the bath, and has the effect of deepening the colour and giving it a golden hue; the quantity of this solution added, of course depends upon the shade of yellow required. For very light shades of yellow, it is necessary that the silk should be perfectly scoured; and if a shade of green is required, some liquor from an indigo vat must be added.

Chromate
of lead.

The chromate of lead is sometimes used for dyeing silk. The hanks, if immersed for a quarter of an hour in a weak solution of acetate of lead, well washed, and dipped in a solution of chromate of potash, will in the course of ten minutes take a fine yellow colour. This article was first employed in dyeing by M. Lassaigne, who published an account of his process in 1820, since which time it has been a good deal used in this Country. From being decomposed by soap and water it is chiefly applicable to silks; by applying, however, a mordant of acetate or nitrate of lead, and passing the goods through bichromate of potash, a very beautiful and sufficiently fast yellow is now given to cotton goods in this Country.

Dyeing
cotton with
weld.

For dyeing cotton yellow with weld, the first thing is to scour it in a bath prepared with the lixivium of ashes of green wood, and then to wash it, dry it, and alum it with the fourth of its weight of alum. After twenty-four hours, it is taken out of the aluming and dried without washing. A weld-bath is now prepared of one part and a quarter of weld to one of cotton, in which the cotton is immersed until the required shade is obtained. It is then taken out of the bath and macerated for one or two hours in a solution of sulphate of copper, and afterwards immersed in a boiling solution of white soap, which, with washing and drying, completes the operation.

Dyeing
with quercitron
bark.

In Dr. Bancroft's process for dyeing yellow with the quercitron bark, 10 pounds of bark are immersed in a proper-sized vessel for six or eight minutes, and a solution of murio-sulphate of tin is added to it, and the mixture stirred for two or three minutes; the cloth must now be put in and kept in motion by two or three men at a winch; the liquor must be made to boil, which will produce, in fifteen minutes, a very good yellow. When a very bright yellow is wanted 7 or 8 pounds of solution of tin, 5 pounds of alum, and 10 pounds of bark are required for 100 pounds of cloth.

In dyeing wool with weld it must be previously boiled in mordants of alum and tartar for one or two hours; for a full yellow 4 or 5 pounds of weld will be required for 1 pound of cloth or worsted. Weld is the most common yellow dye for wool, but the quercitron bark answers very well. In using this substance it is sufficient to boil it with its own weight, or one-third more than its own weight, of alum for ten minutes. The stuff is then introduced, and the deepest shades are given at first, ending with straw-colour. Some dyers boil the stuff for one hour, or an hour and a quarter, in a solution of alum, containing a weight of alum equal to eight times that of the wool, and then dye it in a bath prepared with a weight of quercitron equal to that of the alum, till the colour be sufficiently raised. Dr. Bancroft recommends the use of a solution of tin, as we have described in dyeing cotton.

Mechanical
Processes.
Dyeing
wool yellow.

Many other receipts for dyeing yellow might be enumerated; in fact, they exceed in number those of any other colour, from the great number of vegetables which contain a yellow dye. We might mention, in addition to the above substances, annatto, sawwort, dyer's broom, camomile, fenugreek, turmeric French berries, Canada golden rod, barberry, and a variety of other substances, which have been and are employed in producing yellows of different shades.

Of Green Colours.

(771.) Little is required to be said of these colours, as they are generally produced by the simple mixture of a blue and a yellow bath, or by first immersing the goods in one bath and then in the other, the shade of green depending upon the strength of the baths and the number of immersions. It is, however, with some difficulty produced on silks, as the blue-vat is liable to spot or give a parti-colour. The silk is usually strongly alumed, well washed, and divided into small hanks of about four or five ounces, that it may be easily managed in the working. Weld is boiled as described for dyeing yellow, and prepared strong enough to give a lemon ground; the silk is then immersed and turned, with all the expedition and care possible, that the colour may be even, and when a sufficiently deep colour is obtained the silk is washed and bathed. It is then wrung and formed into hanks, and dipped skein by skein in a blue-vat, which gives it a sea-green. For the dark shades of green a little logwood is added to the liquor, and sometimes old fustic or annatto. For very dark-wavy, or bottle-green shades, a little sulphate of iron is required.

Dyeing silk
green.

In dyeing cottons green, fustic is very commonly employed; they are first passed through a decoction of old fustic and submitted to a green bath composed of fustic, indigo, and weak alum-liquor, which gives a very beautiful green, although rather fugitive. In dyeing a fast green, weld must be used, which makes it a more expensive process.

Dyeing cot-
tons green.

In dyeing wool, a blue ground is generally given by a wood-vat, light or full according to the pattern; the goods are afterwards prepared with alum and tartar, and dyed in a weld liquor. Many of the shades of green are more readily obtained by dyeing the wool first yellow with old fustic and a preparation of alum and tartar, and using the Chemic blue-vat made with the sulphate of indigo.

Dyeing
wool green.

Of Red Colours.

(772.) Cottons are the only description of goods to

Manufac-
tures.

which red colours are generally given. They require for this colour to be very perfectly bleached, or there is a liability to create stains or spots. Even the fine whites on sale are not insured against this evil, and the most careful dyers boil them in a solution of potash, and scour them with sulphuric acid; they must be then galled and well washed. After galling, the cotton must be alumed and dyed in a copper containing crop madder, which is kept boiling for three-quarters of an hour. It must be then aired and washed, and the immersion in the boiler again repeated. Some dye it again two days after, because the longer between aluming, dyeing, and drying, and between one dyeing and another, the better. The second time of dyeing, 8 ounces of madder are used for every pound of cotton. Some dyers gall it twice, and consequently dry it as often, then dye it at once in madder, having a proportion accordingly. This is a red full-bodied colour.

Adrianople
red.

The Turkey or Adrianople red, so celebrated for its beauty and permanency, is also produced by the madder root. In dyeing this colour, the cotton is boiled three hours in a liquor composed of 150 pounds of barilla, 150 pounds of fresh wood-ashes, and 75 pounds of quick lime, in 900 quarts of water, after which it is taken out and dried in the air. A liquor is then formed in the following manner: into 130 quarts of the liquor put 25 pounds of sheep's dung, and part of the intestinal liquor, previously well mixed by means of a wooden pestle, and the whole strained through a hair sieve; 12½ pounds of good olive oil is then added to the mixture, which instantly forms a soapy liquor.

Into this liquor the cotton should be worked hank by hank, often stirring it, and afterwards allowed to remain in the liquor for 12 hours, when it is taken out, lightly wrung, and dried. This process is repeated several times, until the cotton becomes perfectly white, when it is dried and galled with a quarter of pound of galls to every pound of cotton, after which it is dried and alumed 3 or 4 times.

The madder used for the Adrianople red is called *lizary*, which furnishes a dye incomparably finer than that produced by any other madder. In preparing the madder bath a quantity of liquid sheep's blood is well mixed with water in a copper, and ten pounds of *lizary* madder added for every pound of cotton to be dyed. The copper should be carefully secured, and the madder should not be quite brought up to the boiling point. In order to brighten the colour, the cotton is dipped in a lixivium of fresh wood-ashes, and 5 pounds of white soap; when the cotton has been well washed in this liquor, it is, with the liquor itself, put into a copper sufficiently large to hold it with some addition of water, and made to boil, over a slow fire, for 3, 4, or more hours, and the liquor must be covered with coarse white linen cloths, to keep as much steam in as possible. Mr. Packer observes, in his very useful Work, termed the *Dyer's Guide*, that if instead of the wood-ash, lixivium, and soap, the two reserved liquors and soap are used, the red will be much brighter than the finest Adrianople carnation.

Linen yarn takes a colour almost as bright as that of cotton, but it must be passed through a double number of leys and oils.

Of Scarlet and Crimson Dyes.

(773.) The dyeing of scarlet is performed in two opera-

tions; the first is called boiling, the second reddening. A bath is made of cochineal and tartar, which are well mixed together, and some solution, muriate or nitro-muriate of tin, added, and heat applied to the bath. The proportions of these substances should be for 200 pounds of cloth, 10 pounds of tartar, 1 of cochineal, 10 of solution of tin. When the bath begins to boil, the cloth is introduced, and made to circulate rapidly round for two or three turns; the motion is then slackened. After two hours of ebullition it is carried to the river, sifted, aired, and well ashed. For preparing the second bath, the boiler is emptied; 22 pounds of powdered and sifted cochineal are put into it, which is mixed with care and stirred. When a crust is observed to form on its surface, 28 pounds of solution of tin are poured in.

When the solution is well mixed through the bath, the cloth is thrown in, with the precaution of whirling it rapidly for the first two or three turns. It is boiled for an hour, pressing it down into the bath with rods whenever the agitation raises it up. It is then taken out, cooled, and washed in a river, which completes the operation. This same process will answer very nearly for silk or wool, except that the silk must be prepared by aluming. In dyeing crimson, the cochineal is also employed for silk, with about an equal weight of blue and white galls, and boiled in a vessel of grain tin, to which is added about one-half the weight of solution of tin.

The solution of tin employed by dyers is not always the same, some preferring the muriate, and others the nitro-muriate, of tin. Both compositions are readily prepared, by adding a muriate or muriatic and nitric acid to feathered tin, with sal-ammoniac.

Scarlet and crimson colours may be given to wool with a lac dye, which is a great deal used for carpets and hearth rugs. It is dissolved in a peculiar spirit, procured from the drysalts, to about the consistency of treacle, which is then mixed with water in a boiler, and forms the bath. To obtain a scarlet, quercitron bark is added; and for a crimson, archil.

Crimsons may be given to silk by Brazil-wood, by simply immersing it, after aluming, into a strong solution of the wood; it, however, produces a colour much inferior to that of the cochineal.

We have now described the principal processes for dyeing the simple colours; in addition to these there are an immense number of compound colours, such as violet, purple, dove-colour, pansy, amaranth, lilac, from a mixture of red and blue; the maroons, cinnamons, olive, birch, orange, capuchin, &c., from red and yellow. Hazels, snuff-colours, chestnuts, and a variety of browns, from a mixture of black with other dyes. These colours are continually changed, according to the fashion and taste of the time, and every year generally produces some new pleasing colour, sometimes the result of the accidental mixture of dyes, but more frequently that of the researches of our more Chemical and Scientific dyers.

We cannot, without exceeding the limits prescribed to this Essay, enter into a description of the numerous dyes employed in producing the compound colours. We recommend the reader who is desirous of more information on this subject, as well as on other branches of dyeing, to the following Works:

Calico-printing

(774.) The Art of calico-printing differs from that of dyeing, inasmuch that in the latter the whole piece is dyed of one uniform colour, while in the former a portion of the cloth alone is dyed of any desired pattern and colour, without affecting the remainder of the piece.

**Introduc-
tion of cali-
co-printing
into Great
Britain.**

This beautiful Art is of great antiquity, and was carried to great perfection in India. It was introduced into England, in the year 1690, by a Frenchman who, in all probability, was a refugee after the Revocation of the Edict of Nantz, and who established a small print ground on the banks of the Thames, at Richmond. A large manufactory was soon after established at Bromley Hall, in Essex, besides several others in the neighbourhood of London. About the year 1768 or 1769 it was carried into Lancashire, where the trade increased very rapidly, and is now one of the great branches of the cotton manufacture. This Art, by the aid which the advancement of the Science of Chemistry has afforded, has arrived at a state of perfection greatly exceeding that in which it had remained for many centuries in Hindustan, and may now be ranked among the masterpieces of human skill and ingenuity.

The principle upon which the process is founded is that of applying to such parts of the cloth as are required to be dyed a particular mordant, which, when the stuff is immersed in the bath, combines with the colouring matter and causes it to be permanently fixed upon it, while that on the remainder of the cloth is easily removed by boiling in hot water and bran, or by some other bleaching process; but a great improvement has been of late years introduced, termed printing by *resists* and *discharges*. In printing by resists, a substance is applied to the cloth, in the same manner as a mordant, but with this difference, that it is applied to those parts where no colour is required. The cloth is then immersed in a bath composed of a substantive colour, or an adjective colour, mixed with a mordant, which has a natural affinity for the cloth, and combines with it in all parts not influenced by the substance applied, which is of such a nature as to destroy the affinity of the colouring matter, so that when the cloth is washed the colour from those parts is immediately removed, leaving the correct impression of the pattern.

**Printing
by resists.**

**Printing
by dis-
charges.**

In printing by discharges, the pieces of goods are first passed through a mordant, and, before being dyed, a substance termed the discharge is applied to such parts as are required to be white, which has the effect of neutralizing or destroying the effect of the mordant, so that, when the cloth has been dyed, the colouring particles are rendered fugitive upon that part affected by the discharge, and can readily be removed by the usual methods of washing. In producing the great variety of colours which are given to calicoes, these various processes and methods are combined in different ways, and so beautifully arranged, that each mordant, reserve, discharge, and dye, must perform with correctness the duty assigned, as one false step would render useless the time and labour of the operation.

The action of the mordants used by calico-printers

VOL. VII.

admits of the same demonstration as of those employed in dyeing; in fact the Chemical action is exactly the same, although in practice those mordants are preferred which are possessed of great solubility, (whose acid, capable of being volatilized, is united to its base by a feeble affinity;) as these substances can be put upon the cloth in a greater state of concentration, and can be more completely decomposed upon it, more intense and substantial colours can be obtained. Their solubility gives them the further advantage of not rendering the mordant clotty, by a species of crystallization, which takes place during its desiccation on the cloth. For these reasons, the acetates of alumina and of iron, which possess these properties, are the two mordants which are most generally employed by calico-printers. They will produce with different dyes an infinite number of colours.

**Mechanical
Processes.**

**Mordants
used by ca-
lico-print-
ers.**

The acetate of alumina is made by the double decomposition of alum and the sugar of lead, but the proportions of each vary according to the circumstances for which they are intended. In general 3 pounds of alum are thrown into a barrel containing one gallon of pure soft water, at a heat of 150°, and, when dissolved, from a pound to a pound and a half of sugar of lead is added, and the whole frequently stirred for two days. On settling, a clear liquor of acetate of alumina is found at top, which contains alum in solution, and a dense white sediment remains at bottom, which is sulphate of lead, formed by the combination of the sulphuric acid of the alum with the oxide of lead contained in the acetate. Two ounces of pearl ash, and the same quantity of clean powdered chalk or whiting, are then added, which serve to decompose a portion of the salt, whose crystallization in the mordant might have rendered its employment prejudicial. The acetate of alumina is now very frequently made for the calico-printers by dissolving alum in a solution of crude acetate of lime; a gallon of acetate of the specific gravity 1.050 or 1.060 being used with two pounds and three quarters of alum. A sulphate of lime is formed, which precipitates, while an acetate of alumina, mixed with some alum, floats above; the acetate of alumina, employed as a mordant for chintz, is still commonly made by the decomposition of alum and acetate of lead. The other mordant, acetate of iron, is made by the direct solution of rusty iron in vinegar, (acetic acid;) the crude vinegar pyroligneous acid is now usually employed for this purpose in Great Britain.

**Acetate of
alumina.**

**Acetate of
iron.**

To make these mordants fit for printing, and to give them such a consistency as will enable them to dry in a figured pattern, without running into the adjoining parts, they are thickened with paste to the consistency of a jelly, by adding paste, flour, gum arabic, or senegal; 4 pounds of either of the gums being sufficient for a gallon of liquor.

Processes employed in Calico-printing.

(775.) The first process to which calicoes are subjected, after the bleaching, is that of passing them rapidly over the surface of red-hot iron, in order to remove the floss on the surface of the cloth. This operation is generally repeated twice on the side of the cloth on which the pattern is to be dyed, and once on the opposite side. The apparatus by which this is effected consists of a large cylindrical mass of iron, enclosed in brickwork, which also contains a stove for heating it; on each side of the iron are two barrels of wood, lying in a direction

**Singeing
calicoes.**

Manufac-
tures.

parallel to it, and situated below its upper surface. When the iron is sufficiently hot, viz., nearly white hot, the cloth is wound from one of these barrels to the other, which being situated below the upper surface of the hot cylinder causes the cloth to be in contact with the iron through a considerable portion of its circumference, and thus to burn off the floss, which forms a beautiful flame, fluttering on the surface of the iron. It is unnecessary to remark that the motion of the cloth must not be stopped or slackened till the piece is completed, as it would inevitably burn it; in fact, the visitors who witness this curious operation are universally in terror for the safety of the cloth, even at the speed usually employed, and which is by practice found most effective.

Padding
Machine.

The cloth is now ready to receive the mordant, which is put on either by blocks, or by a Machine termed a *padding Machine*, which consists of a frame containing two rollers, the lower of which has the pattern engraved upon it, and revolves in a box containing the mordant; the cloth is passed between the rollers, and the upper one being pressed down causes it to take the impression of the mordant. By the most improved padding Machines two different mordants may be applied at the same time by means of an additional roller, but all varieties of colour or pattern beyond this must be given by blocks.

Printing
by blocks.

The block is a piece of hard wood, generally holly, about a foot long, on which the pattern is carved, nearly as in wood engraving: it is strengthened at the back by adding a piece of thick oak. The parts of the pattern that are to receive a large body of colour, and consequently require a corresponding quantity of mordant, are given by pieces of old hat inlaid into the block, which substance is found to take up the mordant in a more uniform manner than any other material. The finer patterns are sometimes given by sheet copper, fixed on a block like fillagree work, which gives a sharper and finer line to the figured pattern. In making use of this instrument, the cloth is stretched on a long table covered with woollen cloth, and the mordant is placed in a sieve, so that the upper surface lies a little above the surface of the wires of the sieve, leaving a thin coating convenient to be transferred to the printing blocks. The mordant, when naturally colourless, is for blocking tinged with a little Brazil wood, that the workman may see the impression of the cloth, and fix the pattern with accuracy; for this wood, being a fugitive dye, does not impair the general effect. The printer, when at work, first lays the block in the sieve that contains the mordant, then applies it steadily on the cloth, and strikes it a smart blow on the back with a wooden mallet, to give a strong impression; this he repeats successively, each time carefully laying the block in the proper direction, so as not to overlap the last impression.

Drying.

In this way the patterns are impressed with one or more kinds of mordant, as may be required, after which the cloth is strongly dried in a room heated by stoves, which fixes the mordant more firmly on it by volatilizing much of the acetous acid in fumes. This is now sometimes performed by passing the cloth over cylinders heated by steam, which is a much more expeditious process, a whole piece being in this way rendered perfectly dry in the space of a few minutes. It cannot, however, be applied in all cases.

Dung bath. When the mordant is quite dry, the cloth is taken to

a cistern containing very hot water, in which cow-dung is diffused, where it is worked about, in order to dissolve out the paste and other superfluous parts of the mordant, which, not being combined with the stuff, and being diffused in the dye bath, would soil it, both by the combination which it would form with the colouring matter, and by the action of the acid which it might deposit upon it. By not carefully removing the uncombined part of the mordant a two-fold injury would accrue to the cloth, by the impoverishment of the dye bath, and by the covering of the portions which should remain white with the combination. Widmer conceives that there is formed a triple combination of the animal matter with the alumina and the cloth, which improves the beauty of the colours. This opinion, Berthollet remarks, is most probable, since water alone does not produce the effect of dunging, and he endeavoured to find other substances capable of acting in a similar manner; but the only substance he found was a matter analogous to bile. Dr. Ure considers that the action of the cow-dung in calico-printing probably arises from its seizing that portion of the mordant which is not intimately combined with the cloth, thus depriving it of the power of applying itself to the rest of the surface when diffused through the water of the cleansing bath, and thus that some animal principle in the dung, by neutralizing the excess of mordant, and possibly by precipitating it in an insoluble or inert state, protects the unmordanted spaces from being stained or coloured.

After this process, the cloth is rinsed and thoroughly cleaned, after which it is dyed in the usual way, when the whole surface becomes coloured: but the colours are much deeper on the part impressed with the mordant. The colouring matter thus enters into a triple combination with the mordant and the stuff, thereby acquiring the faculty of resisting external agents much more than when it is combined with the stuff without an intermedium. The white colour may in consequence be restored to the parts of the cloth which have received no mordant, by boiling them in water with bran. They are then exposed on a field, observing to lay on the grass the surface of the cloth that bears the colours. By the alternate repetition of these operations, the colouring matters, uncombined with the mordants, are changed in their composition, dissolved, and detached: whereas those which were actually combined, far from suffering deterioration, acquire more lustre.

This destruction of the colouring particles by exposure in the field, and ebullition with bran, is effected in the same manner as that of the colouring particles naturally combined with the stuff, which are removed by bleaching. The differences of the processes consist simply in the substitution of bran for alkalis; because alkalis would dissolve a portion of the colouring matter fixed by the mordant, and would alter its colour: whereas the bran, having a much weaker action on the substance, affects merely the colouring particles rendered soluble by the action of the air. The identity of the nature of this process with those of common bleaching led Widmer to substitute for this method the employment of chlorine, modified by an alkaline solution; the chloride of lime is now used by several English calico-printers for this purpose, but its strength requires to be varied according to the goodness of the white required. From half a pound to a pound of the dry commercial chloride to 100 gallons of water at 180° Fahrenheit may be considered as an average proportion.

Mechanical
Processes.

Dyeing.

Action of
bran in
bleaching

Manufac-
tures.
Action of
different
mordants.

The above is the simple process of calico-printing, in which all the mordants are laid on first, and the colour is given by a single dyeing afterwards, in which a great variety of shades may be produced by merely varying the mordants. Thus, for example, if one pattern be printed with the aluminous mordant alone, a second with a mixture of the former mordant with iron liquor, a third with iron liquor alone, and a fourth with iron liquor and galls, and the piece be afterwards dyed with quercitron or weld, and bleached in the usual manner, the first pattern will be a pure yellow, the second will be olive, the third of a dark drab colour, and the fourth nearly black, while the ground will remain perfectly white.

Cloth which has been thus printed with one course of colours is often subjected to a similar process for a different course with another dye, where the intended pattern requires a great variety of colours. Thus, when all the reds, purples, and browns have been given by a course of madder, the cloth, with part of the patterns thus finished, may be made to undergo a course of mordants to be afterwards dyed with quercitron for other parts of the pattern. In this case, however, much judgment is required to employ only those successions which will not act materially on each other. It might be at first supposed that when a pattern dyed red (for example) with madder, and an alum mordant, came to be immersed in a decoction of weld without any fresh mordant, that the former would not be at all affected by the latter, or at least that the effect would soon be destroyed by bleaching. But this is not found to be altogether the case; for adjective colours appear to have also their relative affinities for mordants; therefore, as fast madder red is a compound of madder and alumina, if madder has a less affinity for alumina than weld, the colour will be in part decomposed, and some of the weld will displace a portion of the madder. Hence the colour will be changed into a triple compound of madder, weld, and alumina, and the dye proportionally altered.

It appears, therefore, that in printing successive courses of colours attention should be paid to print first those whose affinities for the mordants are the strongest, and to finish with the weakest, unless (which is sometimes the case) that the change produced by the intermixture of the colours is part of the desired effect.

Topical
colours.

Another part of calico-printing is the printing of colours directly upon the cloth with the intervention of a mordant: these colours are called topical colours. In this case, substantive colours are generally used; but, if not, the mordant is mixed with the adjective colour previously to its being applied to the cloth in the general dyeing. They are applied to the cloth either by a printing Machine, resembling that employed for the application of mordants, or by blocks.

In some kinds of goods, the topical colours are applied by pencilling or painting, in which case the colour is thickened with gum arabic or senegal, and applied to the cloth with a camel's-hair brush; but in either case the cloths require no other dyeing operation, and are finished by washing and drying, for which reason it is usual to give the last parts of the pattern in this way.

Use of in-
digo in
calico-print-
ing.

Indigo is the only substantive colour used for pencilling; but here a very great difficulty presents itself, in consequence of this dye being a fast colour only in a disoxygenated state, and it is, therefore, very seldom that the pattern of a whole piece can be pencilled in indigo with the same uniformity with which some of the other colours are

given. The solution used for this purpose is usually made of a large proportion of indigo, dissolved in potash, rendered caustic by lime, to which is added orpiment for the deoxygenation of the indigo. The solution is then thickened by gum, and should be kept in a closely-stopped vessel, and no more exposed to air than is necessary for immediate use. The indigo blue is often pencilled upon figures previously dyed yellow, in order to produce a permanent green: but some little injury is done by this means to the yellow ground by the caustic alkali contained in the indigo solution.

Mechanical
Processes.

Adjective colours are sometimes mixed with their proper mordant, and used in a state for pencilling without any other preparation. Such a mixture has, therefore, the effect of a substantive colour. Thus, if a very strong decoction of weld or quercitron is added to a mixture of alum and sugar of lead, and the whole duly thickened, a yellow of a certain degree of durability is formed at once, and may be printed or pencilled on a white ground to produce a yellow, on an indigo ground to produce a green, and on a red madder ground to produce an orange; and thus an immense variety of colours may be produced by topical colours alone.

Adjective
colours.

It is found that adjective colours, when first mixed with their mordants, and when applied to cotton, have very little durability compared to that obtained by the method of first applying the mordant thoroughly, and then the colour. This difference holds good in the general, as well as in topical dyeing of cotton and linen, with all adjective colours, although with regard to wool it appears to be often a matter of indifference, as to the permanency of the colour, whether the mordant and the dye are applied separately or are united. But as this is not the case with cotton it still remains a great object in calico-printing to discover some method of pencilling adjective colours so as to be sufficiently durable. It is also an additional difficulty in this process that the pencilled colours always require a very full body of colour, being generally applied as finishing touches to the pattern which constitutes a very large portion of it.

In addition to the methods of calico-printing above described are those of printing by discharges and resists, which we have before alluded to. When a ground is required to be left white, it is done in the method above described, by leaving those parts untouched by the mordant, so that, when subsequently washed, the dye will be removed on the untouched parts. This plan is, however, obviously inadmissible when the general dye is given by a substantive colour, such as indigo. In such cases, therefore, some kind of covering must be applied to the white pattern parts to protect them from the dye, and to prevent it from penetrating and having some Chemical action upon it, which will destroy its permanency. In the East Indies, wax is often employed for this purpose, and in this Country a mixture of pipe-clay and paste was formerly used. The action of both of these substances is that of preventing the penetration of the colour, but a very common resist now employed is a mixture of sulphate of copper, verdigrise, alum, and gum arabic, thickened with a little pipe-clay, which is printed on the goods exactly like a mordant; this is generally used in dyeing with indigo, and acts by restoring to the indigo the oxygen which it had been deprived of by the sulphate of iron; the oxygenated indigo by this means loses its solubility, and cannot fix itself upon the cloth.

Printing by
resists.

Printing by discharge consists in applying upon the

Printing by
discharge.

Manufac-
tures.

parts of the cloth required to be white some substance which will render the dye fugitive, so that, by the ordinary means of washing, &c., it may be removed. It may be effected in two ways; either by applying some substance on the mordant, previously to the cloth being dyed, which neutralizes or destroys the effect of the mordant at that part, by rendering the colour permanent, or by applying a substance to the cloth after being dyed, which, by a Chemical action upon the colouring matter, destroys its permanency. Another branch of this part of the Art consists in applying to the cloth, previously impregnated with the mordants and dyes, substances which, themselves serving as mordants, modify or destroy the shade which the colouring matter has given, and at the same time receive a colour quite distinct from that on the rest of the cloth.

Mr. Thomson's first
patent.

(776.) These processes had been attempted for many years, both in this Country and on the Continent, but it appears that the first person who succeeded in rendering them practically useful was James Thomson, Esq., F. R. S., of Primrose Hill, who took patents for his inventions in the years 1813 and 1815. The first patent was for a method of discharging the colour from cotton dyed with Adrianople red, which process was as follows:

He mixed with one gallon of good vinegar or rectified pyroligneous acid sufficient starch and flour to render it of the consistency of the mordants commonly used by calico-printers. While boiling hot, 5 pounds of crystallized citric acid are added, and the whole well incorporated by mixing. This paste is printed or otherwise applied to parts of the cloth previously dyed Adrianople red, which were required to be white.

He then prepared a solution of oxymuriate of lime by having dissolved the dry oxymuriate of lime in water, or by passing the oxymuriatic gas into a vessel where he kept a quantity of quick lime suspended by agitation, and thus obtained an oxymuriate of lime with an excess of lime. When the paste on the cloths was dry, the latter were hooked on a frame, such as is used in dyeing indigo or China blues, commonly called a dipping frame, taking care that they were disposed in such a manner that no two folds could touch each other. He plunged this frame with the cloth so attached into a vessel containing the solution of oxymuriate of lime, keeping it gently in motion during the time of immersion, which was generally between 5 and 10 minutes, after which it was withdrawn and rinsed in cold water. The cloths were then freed of the remains of the different substances employed by the ordinary means of washing and branning, and if any of the parts of the cloth intended to be white still retained any colours, they might be cleaned by the usual process of exposure to the air, or by passing the cloth through hot water, to which is added a solution of the oxymuriate of lime. Upon the parts thus rendered white any other colours that are required may be added by the ordinary means of calico-printing.

Mr. Thomson's second
patent.

Mr. Thomson's second patent was for a method of discharging the dye from cloths dyed of any colour by substances which served as mordants in producing other colours. As this invention has proved one of the most important improvements in calico-printing which has been produced for some years, we conceive it may be interesting to the reader to have the description of the invention in the words of the Author, and we have accordingly given the specification of the patent at full length.

"The ordinary practice of calico-printing is to apply,

with the block or pencil, what are termed after-colours to certain spaces, originally left in their patterns, and intended to receive the said after-colours; or to certain spaces on the cloth, from which parts of the original pattern have been discharged, in order to admit, by a subsequent operation, the application of the said after-colours. Now, the object of my invention is by one application of the block, cylinder, roller, plate, pencil, or other mode, to remove parts of the original pattern or colour from the cloth, and at the same time to deposit a metallic oxide, or earthy base, which shall of itself be a colour, or shall serve as a mordant to some colour to be produced, as hereinafter described."

"*First.* Mix or combine with the acid called oxymuriatic acid (or dephlogisticated acid of sea salt) and water the alkaline salts of potash and soda, or, which is still better, calcareous earth or quick lime, in such proportion as will weaken or suspend the power of the said acid, so that it shall not, in such mixed or combined state, of itself and without any further operation, be able to remove or materially to improve the colours within the moderate space of time taken up in the performance of the process.

"*Secondly.* Print, stamp, pencil, or otherwise apply to those parts of the cloth, which are intended to be deprived of one colour and to receive another, a solution of some earthy or metallic salt; the acid of which, having a greater affinity or attraction for the alkaline salt or earth, with which the muriatic acid is mixed or combined, than that acid itself possesses, will disengage it, and the metallic or earthy base of which, being decomposed in the cloth, will either of itself be a colour, or serve as a mordant to some other colour to be produced as hereinafter described.

"*Thirdly.* After the metallic or earthy solution has been printed, stamped, pencilled, or otherwise applied to the cloth, as before directed, and is sufficiently dry, immerse the cloth in a solution of oxymuriatic acid combined with the alkaline salt of potash or soda, or, which I greatly prefer, with calcareous earth or lime, when the acid of the metallic or earthy solution which has been applied to parts of the cloth will immediately seize upon and combine with the alkaline salt or earth with which the oxymuriatic acid has been mixed or combined, and disengage that acid, which will almost instantly deprive of their colour those parts of the cloth to which the said earthy or metallic salt has been applied.

"*Fourthly.* Wash or otherwise remove the said acids or salts by the usual processes, and, when the earthy or metallic base deposited in the cloth is intended to receive another colour, proceed to raise it by the usual operations of dyeing, as will be further illustrated by the examples hereafter given of particular applications of the invention. The earthy solutions which I apply to those parts intended to be deprived of their colour, and to receive another, are the solutions of alumina, or earth of alum, in acids; such, for example, as the sulphate of alumina or common alum, the acetate of alumina, or nitrate or muriate of alumina. The metallic solutions which I employ are the sulphate of iron or copperas: the nitrate, muriate, or acetate of iron, the muriate or nitro-muriate of tin; the sulphate of copper or blue vitriol, or the nitrate, muriate, or acetate of copper. All acids that form soluble compounds with the before-named metals, or the earth of alum, may be employed, but those only which form the most soluble compounds, such, for example, as those enumerated above, can be

Mechanical
Processes.

Manufactures.

employed with advantage. For the more full and complete understanding of the principle laid down in the preceding part of the specification, I subjoin the following practical illustration of its application to various kinds of work. If I desire to have a yellow figure or stripe on a cloth, upon which a maddered ground has been printed; after having by the ordinary processes of calico-printing produced the red ground, or pattern, I first print, stamp, pencil, or otherwise apply to those parts intended to be yellow, a strong aluminous mordant, composed of 3 pounds of sugar of lead, 6 pounds of alum, dissolved in a gallon of water, and thickened with a due proportion of calcined starch, in the manner usually practised by calico-printers.

"*Secondly.* I prepare a solution of oxymuriate of lime, either by dissolving the dry oxymuriate of lime (commonly called bleaching powder or bleaching salts) in water, or by passing the oxymuriatic gas into a vat, vessel, or cistern, in which, by agitation or otherwise, I keep suspended such quantity of quick lime as will more than fully saturate the oxymuriatic gas. In either way I obtain a solution of oxymuriate of lime, with an excess of lime. That which I use and prefer is of the specific gravity 1050, and I seldom employ it lower than 1030 (water being considered as 1000.) The vat, vessel, or cistern, which contains the solution of oxymuriate of lime, in which I immerse the cloth, may be of any size or form best adapted to the purpose or situation. I use and prefer vessels of stone of from 6 to 8 feet deep, 6 to 7 feet long, 3½ or 4 feet broad; but larger or smaller vessels will answer very well.

"*Thirdly.* When the cloth is ready for immersion, which it is as soon as the paste is dry, I hoop it on a frame such as is used in dyeing indigo or China blues, commonly called a dipping frame, on which the cloth should be so disposed that no two folds can touch each other together. I then plunge the frame, with the cloth attached, into the vat containing the solution of oxymuriate of lime, and keep it gently in motion during the time of immersion, which rarely need exceed five minutes. The object being to remove the red dye from certain parts or places, as soon as that is done the cloth should be withdrawn from the solution of oxymuriate of lime, and plunged into or rinsed in cold water. I practise and approve the aforesaid plan of immersion, but any other plan or plans, by which the cloth can be exposed a greater or less time to the action of the oxymuriate of lime, without bringing any part of the said cloth into contact with another part, will answer very well.

"*Lastly.* After having, as before described, rinsed or washed the cloth in clean water, I free it from all superfluous remains of the different substances employed by the ordinary means of washing, dunging, and cleaning, as practised by calico-printers, after which I dye the cloth, and raise the yellow in the usual way with quercitron bark or any other yellow dye.

"If, instead of yellow, it is proposed to have a buff pattern or figure, I add to the aluminous mordant, prepared and thickened as above, one-fourth, or one-sixth, or some intermediate proportion of a solution of nitrate of iron, and proceed to print and immerse in oxymuriate of lime, as in the former case.

"The red dye will be removed as before, and its place occupied by a buff. If the buff be raised in quercitron bark, an olive will be obtained. By printing at separate times, and on different parts of the cloth, each of the above-mentioned mordants, both yellow and olive

figures, on a red ground, may be obtained. Similar effects, with trifling variations, take place when, instead of red grounds, purple or chocolate grounds are employed, but it must be observed that these colours, being produced from mordants, consist, wholly or in part, of solutions of iron, and the oxide of that metal not being removable by the process detailed in the specification, the after-colours put on will be modified more or less by the said oxide of iron. The foregoing examples are given for the more full explanation of the said invention, and the manner in which it is to be performed; but the invention, whereof I claim the sole and exclusive use, consists of printing, stamping, pencilling, or otherwise applying to cloth, previously printed and dyed, Turkey red or any other colour, any of the earthy or metallic solutions, as above directed, and immersing the whole cloth in such mixture or combination of oxymuriatic acid with water, with some of the alkaline salts or earths, as is herein directed for that purpose, so as to remove the colour or pattern from the part so printed, stamped, pencilled, or receiving such application, and, by the same process, fix on such parts either a new colour, or a mordant for a new colour."

(777.) Having thus given a general outline of the different styles of calico-printing, we purpose, as far as our limits will permit, to describe the mordants and dyeing substances made use of in producing the principal colours.

First. Printing by the application of mordants to the parts of the cloth required to be coloured.

Black colours.—The mordant employed for this colour is acetate of iron, commonly called iron liquor, produced by dissolving iron in vinegar. Some calico-printers employ copperas, and some other substances mixed with it. M. Vitalis gives the following receipts:

1st. Dissolve 4 ounces of copperas in 12 pints of iron liquor, and, after having decanted the clear part, add 4 pounds of starch, and heat the mixture in a boiler, taking care to stir continually, until the starch is well boiled.

2d. Mix 2½ pounds of superfine wheat-flour in 8 pounds of iron liquor. It must be mixed very gradually, adding a portion of the liquor at a time, and left to rest for 12 or 24 hours. It is then to be boiled for about half an hour, until the mixture has acquired the consistency of a paste, and then removed from the fire until it becomes cold.

The dye which gives the best black with these mordants is logwood and madder. Sumach and some other dyes will also produce a black, but by no means equal in beauty and intensity. Purple is given by the same mordant diluted with water.

Red.—The mordant commonly used is composed of a solution of 3 pounds of alum in a gallon of water, one-half of which is decomposed by the acetate of lime or lead. M. Vitalis gives the following:

150 pounds of pure alum is to be boiled with 3 pounds of ground Brazil wood, which must be stirred until the alum is dissolved, and 50 pounds of acetate of lead added. When the liquor begins to clarify, 6 pounds of the potash of commerce and 6 pounds of chalk are added, and the whole left for an hour to settle.

For strong reds the above mordant is thickened with starch, and, if lighter reds are required, it is thickened with gum, which must be varied in quantity according to the strength of the red required.

The dyes employed for reds are madder and sumach.

Mechanical Processes.

Manufac-
tures.

Prussian Blue.—The same mordant is used as for black, with a dye of prussiate of potash, in which the prussic acid has been set free by means of sulphuric acid.

Yellow.—Mordant used is the same as for red. The piece when slightly dunged is dyed for about one hour with one pound of quercitron bark, the infusion being gradually heated during that time from 130° to 160°.

Drab.—Mordant, dilute acetate of iron, and thickened with gum. Dye, quercitron bark.

Olive.—Mordant of the fast red mordant, with acetate of iron. Dye, quercitron bark.

Coffee Colour.—Mordant, 2 pints of the second red mordant with 2 pints of acetate of iron liquor. Dye, madder.

Puce or Carmelite Colour.—Mordant, 3 pints of the second red mordant with $\frac{1}{2}$ pint of acetate of iron liquor. Dye, madder.

Deep Brown.—Mordant, 3 pints of the second red mordant with $\frac{1}{2}$ pint of iron liquor. Dye, madder.

Violets.—Mordant, 16 parts of iron liquor with 8 pints of water and 4 ounces of Roman vitriol. The mixture to be thickened with powdered gum in the proportion of a pound to a pint. Dye, madder.

Maroon or Chestnut Brown.—Mordant, 2 pints of violet mordant with 1 pint of red mordant and 8 ounces of green copperas. Dye, madder.

Lilac.—Mordant, 1 pint of violet mordant with 1 pint of the mordant for light red. Dye, madder.

Topical
colours.

Printing by Topical Colours.—This method consists in applying the colour to the cloth after it is mixed with the mordant, by which a great deal of time and labour is saved, but the colours obtained by this means are much less permanent than those produced by the previous application of the mordant. These are called topical or chemical colours. They require no further process, after their application to the cloth, but that of washing in order to remove the gum or starch mixed up with the colour.

Topical Black.—A very good black may be produced by a decoction of logwood and galls thickened with flour, and when cold, nitrate of iron mixed with it. Vitalis gives the following :

1st. To 12 pints of acetate of iron add 4 ounces of Roman vitriol dissolved in water, and a quantity of the decoction of galls. Thicken with $3\frac{1}{2}$ pounds of starch, which is to be gradually worked up with a portion of the liquor. After it has boiled withdraw it from the fire and keep stirring till the liquor is cool ; it must then be strained through a sieve or linen cloth.

2d. Boil 2 pounds of logwood, 2 pounds of sumach, and 8 ounces of galls in 24 pints of water, till the liquor is reduced to half its volume. Add then a pint of the acetate of iron liquor, boil away 6 more pints, and take off the clear part of the bath. In this, dissolve 2 ounces of Roman vitriol, and 1 ounce of sal ammoniac ; after which thicken with starch and pass it through a sieve as before.

Pencil Blue.—This is the most important of the topical colours, and requires no further substance mixed with it to serve as a mordant, being obtained from indigo, which is a substantive colour. It is generally prepared in the following manner :

Boil in 10 gallons of water 7 $\frac{1}{2}$ lbs. of quick lime, and 15 lbs. of potash. Decant off the clear liquor, and separate the remainder from the lime by means of a filter. To 1 gallon of this solution add 1 pound of

sulphuret of arsenic (orpiment) and 1 pound of fine indigo, both previously ground together in a mill, with sufficient water to make a thick paste. Bring them gradually to boil, stirring carefully all the time, and then withdraw the fire. Thicken the solution with the best gum senegal, and for the pale shades of blue dilute with one or two measures of gum water.

The quantities and relative proportions of potash, orpiment, and indigo in a gallon of pencil blue, vary considerably with different calico-printers, and within certain limits it appears that the accuracy of these proportions is not of great importance. The solution when first made is a yellowish-green, and becomes gradually deeper, and at last blue, by exposure to the air. It must be preserved very carefully from the air, as, should it become blue, it contracts no union with the cloth, and is detached from it in the first operation of rinsing.

Another blue, less permanent, but more brilliant, is now very commonly preferred. It is made with Prussian blue, ground very fine, and mixed with muriatic acid to the consistency of a sirup. The mixture requires to be stirred every day for an hour, and afterwards thickened with gum water according to the shade wanted.

Reds.—The pale and more delicate shades of red are those chiefly sought after in calico-printing, as they are generally employed in giving relief to colours of a more sober cast ; and all the skill of the colour-maker is exerted in giving them brilliancy and richness of tint. They are chiefly produced from decoctions of Brazil, Nicaragua, or pearl wood, and cochineal, raised and fixed on the cloth with solutions of tin. The following is the method of preparing the colour with Brazil wood :

Boil 10 pounds of chips of Brazil wood in as much water as will cover them, draw off the decoction, pour on fresh water and boil as before, add the two liquors together, and evaporate slowly down to 1 gallon. To the decoction while warm add 4 ounces of sal ammoniac, and as much gum dragon or senegal as will thicken it for the work required. A solution of tin is prepared by dissolving 2 ounces of sal ammoniac in 1 pound of nitrous acid, of specific gravity 1.25, and adding 2 ounces of fine grain tin. The colour must be carefully decanted, and diluted with one quarter of its weight of pure water. A solution thus prepared is sufficient for 4, 6, or 8 gallons of the Brazil liquor, but the proportion is varied according to the shade required. When put upon the cloth it must be suffered to remain from eighteen to twenty-four hours ; the colour will be a pale and delicate pink. Nicaragua, or pearl wood, although not so rich in colouring matter as Brazil, yields a tint which, if possible, is more delicate and beautiful.

Scarlet colour is prepared from cochineal in the following manner : Add to one gallon of water 1 pound of cochineal ground as fine as flour, boil half an hour, and add 2 ounces of finely-pulverized gum dragon and 2 ounces of cream of tartar, and stir till the whole is dissolved. When the liquor is cool add one measure of the above solution of tin to two of the cochineal liquor, and incorporate them well by stirring.

Yellows.—These are generally prepared from French or Turkey berries or quercitron bark. This latter substance produces pale yellow or straw colour, but does not afford the deep bright orange yellow of the berries.

Berry yellow may be made by boiling two pounds of good berries slightly bruised in a gallon of water during three hours, taking care to replace from time to time the evaporated water with liquor obtained from the second

Mechanical
Processes.

Manufactures.

boiling of a former quantity of berries. When the liquor is cool add to it 8 ounces of alum, and if it is intended for the blocks thicken it with flour, and if for the pencil 2 ounces of sugar of lead should be added with the alum, and the colour thickened with gum dragon. This yellow is generally passed through lime water as the first operation of rinsing, by which means the greater part of the earth of the alum, which would otherwise have been carried off in the operation, is precipitated on the cloth and the colour considerably heightened.

The straw or lemon yellow is made by boiling 4 pounds of quercitron bark in 8 pints of water until the decoction is reduced to half its original bulk. This must be thickened with 3 pounds of gum added gradually. A solution of tin, composed of a mixture of 3 ounces of muriatic acid, 4 ounces of nitre, and 4 ounces of pure water, with 2 ounces of grain tin, must be added, which renders the colour of a brilliant yellow. This yellow resists vegetable acids very well, and, when placed on a blue ground, forms a very fine green. By mixing with it a little of annatto bark good orange yellows will be produced.

A yellow termed rust yellow is made with acetate of iron thickened with gum for light yellows, and with starch for the deeper shades. Rust yellow, when applied on blue, gives a deep green which serves for the stems of certain flowers. A beautiful yellow is also now produced by the chromate of lead.

Green.—The colour is very commonly produced by the mixture of the topical blue and yellow, in which the yellow predominates considerably. A very fine green may also be produced by putting upon the cloth a solution of sulphate and acetate of copper, and passing it through a strong solution of potash in which some protoxide of arsenic has been dissolved.

Purple.—If the solution of tin directed for the red be mixed with six times of its bulk of a decoction of logwood, poured while hot upon four ounces of sal ammoniac, and 2½ pounds of gum senegal, a bright and lively purple will be obtained, the hue of which varies with the strength of the decoction and the proportion of the solution of tin employed. Various shades of purple may also be produced by using different proportions of the acetate of alumina instead of the solution of tin.

Orange.—The solutions of iron in vinegar strengthened by the addition of copperas will produce this colour, but the purest and brightest gold colours are obtained from copperas and sugar of lead, in the proportion of 5 pounds of the former and 1 pound of the latter to a gallon of water. When thickened with gum and employed undiluted it affords, when limed, a full strong gold colour, and with two, four, six, &c. times its bulk of water, various shades of orange and buff, which resist the action of the air, alkalis, and soap, and are rather exalted and improved by frequent washing.

A beautiful but fugitive orange may also be obtained by boiling ½ a pound of annatto with 1 pound of caustic potash in a gallon of water, and thickening the liquor with gum. This colour, however, acts very powerfully on the sieves and blocks, which it soon destroys, and on this account, and also from its want of permanency, is seldom used.

Violets.—These are variously compounded according to the colour required.

1st. By mixing chemical black in various proportions with berry or bark yellow. The depth and fulness of the colour depend on the quantity of black.

2d. By a decoction of logwood added in a greater or less proportion to the bark or berry yellow.

3d. By the addition of copperas or nitrate of iron to decoctions of yellow or astringent colouring matters, such as bark, sumach, weld, &c., each of these produces a different hue, varying from a green colour to a drab or cloth colour. By mixing these decoctions in different proportions, and by varying their strength, and the quantities of copperas or nitrate of iron added to each, a multiplicity of shades may be produced, of which it is impossible to convey any precise or definite idea.

We have now explained the methods usually employed of producing the principal colours, both by the previous application of the mordant, and by the addition of the mordant previous to the application of the colour.

In the practice of calico-printing these two modes of colouring are very frequently combined in the same piece when a number of different colours are required.

(778.) The reader will form a good idea of the mode of managing different styles of calico-printing from the following example given by Vitalis.

Calicoes of one Block.

First example.—Violet on a white ground.

1st Operation. The impression of the violet mordant.

2d. Dyeing and washing.

3d. Dyeing in a madder bath.

4th. Branning and exposure on the grass to clear the grounds.

Second example.—Black on a yellow ground.

1st Operation. Bath of yellow mordant.

2d. Dyeing in a weld bath.

3d. Impression of topical black.

Calicoes of two Blocks.

First example.—Two olives on a white ground.

1st Operation. Impression of the first olive mordant.

2d. Impression of the second olive mordant.

3d. Dyeing in a weld bath.

Second example.—Red and blue on a white ground.

1st Operation. Impression of the red mordant.

2d. Dyeing in a madder bath.

3d. Impression of topical blue.

Third example.—Yellow and black on a white ground.

1st Operation. Impression of the yellow mordant.

2d. Dyeing in a weld bath.

3d. Impression of the topical black.

Calicoes of three Blocks.

Example.—Two olives and a yellow on a white ground.

1st Operation. Impression of the first olive mordant.

2d. Impression of the second olive mordant.

3d. Impression of the yellow mordant.

4th. Dyeing in a weld bath.

The third block might also be performed by the impression of the topical yellow.

Calicoes of four Blocks.

Example.—Black, red, violet, and yellow, on a white ground.

1st Operation. Impression of the black mordant.

2d. Impression of the red mordant.

3d. Impression of the violet mordant.

4th. Dyeing in a madder bath.

5th. Impression of the yellow mordant.

6th. Dyeing in a weld bath.

Mechanical Processes.

Printing calicoes with one block, and with two or more blocks.

Manufac-
tures.

The last colour might have been given equally well by a topical yellow.

Calicoes of five Blocks.

Example.—Black, red, violet, yellow, and blue, on a white ground.

- 1st Operation. Impression of the black mordant
- 2d. Impression of the red mordant.
- 3d. Impression of the violet mordant.
- 4th. Dyeing in a madder bath.
- 5th. Impression of the topical blue.
- 6th. Impression of the topical yellow.

Calicoes of six Blocks.

Example.—Two olives, black, two reds, and yellow, on a white ground.

- 1st Operation. Impression of the black mordant.
- 2d. Impression of the first red mordant.
- 3d. Impression of the second red mordant.
- 4th. Dyeing in a madder bath.
- 5th. Impression of the first olive mordant.
- 6th. Impression of the second olive mordant.
- 7th. Impression of the yellow mordant.
- 8th. Dyeing in a weld bath.

In all the examples above given the cloth must be finally branned and exposed in the fields to clear the grounds. When topical colours are employed this process must be performed previously to their application. The impression of the first mordant is now generally given by the padding Machine, and the mordant of that colour is chosen which is most prevalent in the pattern; sometimes the first two mordants are given by this Machine, but beyond that number they must be performed by blocks. The greater part of the common calicoes, which contain only one or two colours, can be done entirely without the use of blocks, and thus a great deal of labour is saved, and the price of the article, consequently, greatly reduced. When a great number of colours are given, the quantity of labour is greatly increased, and the price of the articles bears no proportion to that of the simple patterns. A great number of colours may be given to cotton goods at a little expense by the topical colours, but they will not stand washing, and are, consequently, much less valuable for all the ordinary purposes.

Printing by Resisting Pastes.

Printing by
resists

(779.) The resists are generally used in blue-dipping; they are printed on the goods like the mordants, and four-and-twenty hours after the impression the goods are passed through the dyeing-vat, and after washing, the parts where the paste has been applied become white. Vitalis gives the following receipt for resists:

"Dissolve in 2 litres (a little above a quart) of water 4 ounces of sulphate of copper, and 6 ounces of verdigrise, to which add 1 pound of gum arabic, and when it is dissolved pass through a fine sieve, and let it set and decant. The bath is thickened by a pound of pipeclay, well ground, sifted, and kneaded, with 3 or 4 ounces of water. It must be mixed very carefully in the bath, and well triturated before being made use of."

Action of
the resist.

The oxide of copper, which forms the basis of the resist, restores to the indigo the oxygen which it has been deprived of by the sulphate of iron. The oxygenated indigo loses its solubility, and consequently

cannot fix itself on the stuff. Since the resist intended to nullify the action of the indigo acts merely by the oxide of copper which it contains, it follows that the proportions of the oxides are not indifferent, and that the measure will not perfectly accomplish its end, unless the dose of oxide of copper, which the sulphate can furnish, be adequate to neutralize the action of the indigo. A similar result will ensue if the resist be not suitably thickened. The proportions of cupreous salts ought to be as little as can be to effect the purpose, as if their quantity be too great their operation would be extended to the indigo diffused throughout the bath.

The following examples will illustrate the manner of managing this style of printing:

To make a Sky-blue on a Dark Blue.

- 1st Operation. Dye the cloth in a sky-blue vat.
- 2d. Apply the resist on the parts intended to be sky-blue.
- 3d. Dye the cloth in a dark blue vat.
- 4th. Immerse it in a bath acidulated with the oil of vitrol, or muriatic acid, in order to carry off the particles of lime suspended in the vat.

Sky-blue, Dark Blue, and White.

- 1st Operation. Apply the resist to the parts intended to be white.
- 2d. Dye the cloth in a sky-blue vat.
- 3d. Apply the resist on the parts intended to be sky-blue.
- 4th. Dye the cloth in a dark blue vat.
- 5th. Immerse in acidulated water.

Deep Blue, Sky-Blue, Green, Yellow, and White.

- 1st Operation. Apply the resist to the parts intended to be white and yellow.
- 2d. Dye in a light blue vat, and dry.
- 3d. Immerse in water acidulated with sulphuric acid to brighten the colour, and wash and dry.
- 4th. Apply the resist to the parts intended to be light blue and green.
- 5th. Dye in a dark blue vat, and brighten.
- 6th. Apply the red mordant on the parts intended to be yellow and green.
- 7th. Dye in a bath of weld or quercitron.

The white portions which were impressed with the mordant will become yellow, the blue parts impressed with the red mordant green, while the parts left untouched by the mordant will come out, by washing and branning, white, light blue, and dark blue.

Printing by Discharges.

(780.) Little further is required to be said on this subject, as the methods of accomplishing this branch of calico-printing have been pointed out at considerable length in the specification of Thomson's patent, given in the preceding part of the Essay. In printing with discharges on a mordant, the discharge is prepared with nitric, citric, oxalic, or tartaric acid, or bisulphate of potash thickened with roasted starch. It is necessary that the mordant previously put on the goods be made very dry by passing them over the steam cylinders; the discharge is then applied by means of the padding Machine used for mordants, and the goods well washed and exposed on the grass. This style is most frequently used for mourning garments, composed of a figure on a

Mechanical
Processes.

Printing by
discharges.

Manufactures. black ground ; but figures may, by the same process, be readily obtained on a ground of red, violet, or any other colour.

White discharge on indigo grounds.

A neat and expeditious style of discharge work on indigo grounds has of late years been extensively employed by calico-printers in this Country. A paste is made with aquafortis and pipeclay, which is applied by a cylinder of wood having the pattern cut upon it. The cloth, immediately on receiving the impression, is passed through a strong body of steam, issuing from a row of small orifices in a horizontal box. The high temperature gives blanching energy to the nitric acid, and the accompanying moisture dilutes it so as to prevent corrosion of the cotton fibres. The safety of the goods is ensured, however, by a thorough washing.

Discharges on dyed goods.

The parts rendered white by the above processes may be dyed of any colour, either by the application of a mordant, or by topical colours. When, however, the discharged part of the cloth is required to be coloured it may be accomplished with fewer processes, and much better by the methods pointed out by Mr. Thomson ; for instance, if it is required to have yellow figures on an olive ground, a discharge must be found which, in destroying the colour communicated by the iron, will at the same time change the colour to yellow. This may be effected by a solution of tin, prepared by adding a little muriatic acid to a solution of muriate of tin, and afterwards carefully thickening with starch previously boiled, to insure the thorough union of the ingredients. The goods must then be immediately washed, to prevent the discharge acting too long on the colour, and the parts impressed with the mordant will be found changed to a good yellow colour.

Scarlet on a black ground.

In the same way, if calico has been dyed black in a logwood-bath mixed with iron liquor, if any parts be impressed with a solution of tin, the ferruginous parts touched with the discharge will be removed and will pass from a deep black to a very brilliant crimson. By subjecting to the same treatment calicoes dyed of different colours and shades, determined by different degrees of oxidation of the iron, a great variety of shades and colours will be produced.

Green on a blue ground.

A beautiful green may be produced on a blue ground by dyeing the cloths first with a pale blue in an indigo vat, passing them through a bath of sumach and sulphate of iron, and finishing in a bath of quercitron with alum. The green colour produced by the indigo

and quercitron remains masked, as well as the other Mechanical Processes. colours, by the oxide of iron in the sulphate until the solution of tin be applied, which causes the other colours to disappear, and gives to those that remain a lustre which they would not otherwise have had, because the solution of tin renders the quercitron yellow more vivid, and because from this vivid yellow associated with the blue results a more brilliant green.

Calico-printers make use of these methods, combined with that of mordants, in producing more readily some varieties of colours, as will be understood from the following examples :

First example.—Olive, yellow, and white.

1st Operation. Immersion in the olive mordant.

2d. Impression of the white discharge, wash and dry.

3d. Dyeing in a weld bath.

4th. Impression of the yellow discharge, and wash.

Second example.—Bright red and dull red : white, yellow, and black, on an olive ground.

1st Operation. Impression of the red mordants.

2d. Dyeing in a madder bath.

3d. Application of reserves or resists on the reds.

4th. Immersion in the olive mordant.

5th. Impression of the white discharge.

6th. Dyeing in a weld bath.

7th. Impression on the yellow discharge.

8th. Impression of the topical black.

If, instead of applying the yellow discharge, thickened as usual with starch, one-third more starch be employed, and a colouring of decoction of Turkey berries or Brazil wood be added, there will be obtained, in the first case, a richer yellow, and, in the second, an orange-yellow.

We might enumerate many other combinations of the different styles of calico printing which are had recourse to in producing the great variety of beautiful colours which these goods present, the extent assigned for this Essay will not, however, permit us to enter at greater length on this subject ; and we beg to refer the reader for further information to Dr. Ure's Notes to his Translations of Berthollet's *Chemistry*, Parke, *Chemical Essays*, and to Vitalis on *Dyeing*.

(781.) The advance which the Art of calico printing has made within a few years will be illustrated by the following Table, in which is stated the quantities of printed and dyed cotton exported from this Country, distinguishing the various Countries to which they were imported, for each year, from 1820 to 1831, both inclusive :—

Countries to which exported.	1820.		1821.		1822.		1823.		1824.		1825.

Tanning.

Tanning.

(782.) Tanning is the Art of impregnating the hides of animals with a substance termed *tannin*, usually obtained from oak bark, which, by a peculiar Chemical action it exerts on the gelatinous part of the skins, renders them impervious to water and not liable to decomposition.

It is difficult to say at what period the Art of tanning

was discovered, for something of the kind must have been practised at a very early period, as the skins of beasts which certainly formed the first covering of Man would, without some such process, have become putrid and useless; and it, accordingly, appears that the Ancients possessed the tanning Art in some degree of per-
fection.

Manufactures.

The astringent matter which converts the skin into leather abounds in so many vegetables in every Country, that accident would soon lead to some method of producing the change. Independently, however, of vegetables, many mineral substances have the property of rendering the skins incorruptible to a certain extent, and some mineral waters containing copper or iron will produce the same effect. Hence we may conclude that some means of giving preservation to the skins of animals must have been known at a very early period.

Of late years considerable changes have taken place in the modes of tanning, so that this operation, which a few years ago took several months to complete, can now be done in as many days. The time thus saved is, of course, of great importance to the tanner, as it enables him to sell the manufactured article at a lower price. The leather, however, made by this hastened process is considered to be less perfect than by the old method, an opinion which is supported by many eminent tanners and scientific men, among whom may be mentioned Sir Humphrey Davy, who devoted a great deal of time to the investigation of this subject. Parts of the hide which are hard have not time to become perfectly saturated with the tanning liquor, so that an irregularity in the quality of the leather is produced; for which reason a great number of tanners still continue the old system, and this advantage allows them, in some measure, to compete with those who employ the quicker process.

Theoretical remarks on tanning.

Theory of tanning.—Before entering into a description of the manual operations of tanning, we propose to make a few remarks on the Chemical nature of the process, a subject which has engaged the attention of some of the most eminent Chemists, among whom Seguin was the first who ascertained the peculiar vegetable matter which is essential to this process, and which is possessed of the characteristic property of precipitating gelatine from its solutions. Mr. Proust has since investigated many other properties of this substance, but neither these nor any other Chemists have yet carried their investigations so far as to determine the various affinities of tannin, and especially how its action upon vegetable matters is modified by combination with other substances. This task was reserved for Sir Humphrey Davy, who bestowed, for an interval of two years, the chief part of his leisure time on a course of experiments on this subject, which he laid before the Royal Society, who published the results in their Transactions for the year 1803. As the Paper contains a great deal of matter both serviceable to the practical tanner, as well as interesting to the scientific Chemist, we avail ourselves of the abstract published by the Society, which elucidates the principal facts in a very complete and concise manner.

Sir Humphrey Davy's experiments.

(783.) The Paper consists of five parts, the titles of which are as follows:—1. Observations on the Analysis of Astringent Vegetable Infusions. 2. Experiments on the Infusion of Galls. 3. Experiments on Catechu. 4. Experiments and Observations on the Astringent Infusion of Barks, and other Vegetable Productions; and, 5. General Observations.

Analysis of vegetable infusions.

1. *As to the analysis of vegetable infusions.*—The substances which have been supposed to exist most generally in them are tannin, gallic acid, and extractive matter. The presence of tannin in an infusion is known by the precipitate it forms with gelatine, such as glue or isinglass; but the process requires many and very delicate precautions. Previously to the experiments the in-

fusions are materially affected by exposure to the atmosphere: the tanning principle in different vegetables demands for its saturation different proportions of gelatine, and the quantity of precipitate obtained by filtration is not always proportionate to the quantity of tannin and gelatine in the solution, but is materially influenced by the degree of their concentration. Hence it follows, that the solutions of gelatine for the analysis should be employed in as high a state of saturation as is compatible with their perfect fluidity. They should be used only when quite fresh, and, as their relative effects were found to be influenced by their temperature, it was found expedient to bring them, and the infusions on which they were designed to act, as nearly as possible to a common degree of temperature: great care must also be taken to prevent any excess of gelatine.

Duly attending to all these precautions the general result is, that in any given case where the quantity of gelatine in the solution employed upon an astringent infusion is compared with the quantity of precipitate obtained, the difference between them may be considered as the proportion of tannin contained in the infusion.

The tannin being thus separated, it remains to ascertain the proportion of the two other ingredients in the infusion by gallic acid and the extractive matter. The first step here was slow evaporation, by which the latter substance is in part rendered insoluble so as to subside at the bottom of the vessel. A proportionate quantity of alcohol being next poured upon the fluid, thus reduced to a thick consistency, both the gallic acid and the soluble extractive matter, if there were any remaining in the infusion, was dissolved. The great difficulty now was to separate the gallic acid and the extractive matter. Ether and alumina were tried without the desired effect, the affinities of these two agents with those substances not being sufficiently distinct to produce the separation. Some judgment may, however, be formed by means of the salts of alumina and the oxygenated salts of iron. Muriate of alumina precipitates much of the extractive matter from the solutions without acting materially upon the gallic acid; and after this precipitation some idea may be formed concerning the quantity of gallic acid by the colour it gives with the oxygenated sulphate of iron.

2. *Concerning the infusion of galls.*—The strongest solution of galls was obtained by repeatedly pouring distilled water upon the best Aleppo galls broken into small pieces; it was of the specific gravity 1.068°; 400 grains of the solution produced by evaporation, 53 grains of solid matter, which, as well as could be estimated by the methods of analysis described in the preceding section, consisted of about $\frac{9}{10}$ of gallic acid united to a minute portion of extractive matter. One hundred grains, moreover, of this solid matter left, after incineration, nearly $4\frac{1}{2}$ grains of ashes, which were a mixture of lime with carbonate of lime and a small portion of fixed alkali.

Infusion of galls.

Here follows a long series of experiments on the infusion of gall-nuts, in which it was exposed to or combined with all manner of chemical agents, viz. sulphuric, muriatic, and nitric acids, potash, soda, ammonia, and a variety of alkaline earths, magnesia, alumina, different solutions of neutral salts, metallic oxides, and other substances, the list of which is too long to be here inserted. Many of the results may be considered as insulated facts, but those who attend to inquiries of this nature will find most of them connected with useful

Manufac-
tures.

conclusions, tending to elucidate this obscure, but, no doubt, very interesting part of Chemistry. The ultimate result of these experiments, as to the constituent parts of gall-nuts, is that 500 grains of good Aleppo nuts gave, by lixiviation with pure water, till all the soluble parts were taken up, 185 grains of solid matter, and that this matter, examined by analysis, consisted of

Tannin.....	130
Gallic acid with a little extractive matter	35
Mucilage and matter rendered soluble by evaporation	12
Calcareous earth and saline matter.....	8
	—
	185

A piece of dry calf-skin, perfectly free from extraneous matter, that weighed 180 grains after being prepared for tanning by long immersion in water, was tanned in a portion of the infusion being exposed to it for three weeks. When dry the leather weighed 295 grains, so that, considering this experiment as accurate, leather quickly tanned, by an infusion of galls, consists of about 61 grains of skin and 39 of vegetable matter in 100 grains.

After depriving a portion of the infusion of all its tanning matter, by repeatedly exposing it to the action of pieces of skin, it was found to give a much lighter colour to oxygenated sulphate of iron than an equal portion of a similar infusion, which had been immediately precipitated by solution of isinglass, which Sir Humphrey Davy was rather inclined to attribute to the decomposition of the gallic acid by exposure to the atmosphere than to its absorption by the skin.

Extract of
catechu.

(784.) 3. *On the extracts of catechu, or terra Japonica.*—This extract is said to be obtained from the wood of a species of mimosa, which is found abundantly in India, by decoction and subsequent evaporation. There are two kinds, the one sent from Bombay and the other from Bengal, which somewhat differ from each other in their external appearance, but very little in their Chemical composition. The tastes of both are sensibly astringent, and neither of them deliquesces, or is apparently changed by exposure to air.

Sir Joseph Banks, at that time President of the Royal Society, was the first person who, noticing the more obvious qualities of this substance, suspected it contained the tanning principle, and being possessed of a quantity of it, he supplied Sir Humphrey Davy with all he wanted for the purpose of Chemical examination. The first experiments showed that its solution copiously precipitated gelatine, and that it speedily tanned skins; and hence he was encouraged to undertake the particular investigation of its properties, the account of which is the subject of the present section.

His mode of proceeding, of course, could not differ materially from that which he adopted in the analysis of the gall-nuts, and indeed most of the same, and some additional Chemical agents, have been put to the test. The ultimate analysis has been attended with some difficulty, different specimens of this substance, though to all appearance quite pure, differing materially among themselves; the natives, for the sake of profit, being apt to adulterate what they sell either with sand, earthy substances, or other extraneous matter.

Sir Humphrey Davy, in order to obviate this difficulty, selected a number of specimens, such as he had reason to think the least tainted, and, having reduced

them into powder, he found the two sorts to consist of the following ingredients:—200 grains of the extract of catechu from Bombay consisted of

	Grs.
Tannin	109
A peculiar extract matter	68
Mucilage	13
Residual matter, chiefly sand and calcareous earth	10
	—
	200

The same quantity of the extract from Bengal yields

Tannin	97
Peculiar extractive matter	73
Mucilage	16
Residual matter, viz. sandy, with a small quantity of calcareous and aluminous earth .	14
	—
	200

With respect to the application of this substance to tanning, Sir Humphrey Davy made the following experiments. Of two pieces of calf-skin, which weighed when dry 132 grains each, and which had been prepared for tanning, one was immersed in a large quantity of the infusion of the extract of catechu from Bengal, and the other in an equal portion of the infusion of the extract from Bombay. In less than a month both were found converted into leather, and when freed from moisture by long exposure to the sun they were weighed. The first piece had gained about 34 grains, and the second piece 35½ grains. The colour of the leather was much deeper than that tanned, and on the upper surface it was of a reddish-brown. It was not acted upon by hot or cold water, and its apparent strength was the same as that of similar leather tanned in the usual manner.

In examining the remainder of the infusions of the catechu, in which the skin had been converted into leather, he found in them much less extractive matter than might be expected from the comparative analysis of equal portions of the unaltered infusions made by solutions of gelatine. At first he was inclined to suppose that the deficiency arose from the action of the atmosphere upon the extractive matter, by which a part of it was rendered soluble. But in considering that there had been very little precipitation in the process, he was led to adopt the supposition that it had entered into union with the skin at the same time with the tannin, and this supposition was confirmed by further experiments.

(785.) 4. *On the infusion of barks and other vegetable productions.*—The experiments described in this section were chiefly made on the strongest infusions of the bark of oak, Leicester willow, and Spanish chestnut; each of them were nearly of the specific gravity of 1.05. Their tastes were alike strongly astringent. 200 grains of each, submitted to evaporation, yielded

of barks.

Manufac-
tures.

calcareous earth and alkali, the quantity being greatest from the matter produced from the chestnut bark.

These several infusions were acted upon by the acids and pure alkalis in a manner very similar to that adopted with the infusion of galls. No gallic acid whatever could be obtained from any of them, and, if any be contained, it must be in a state of intimate combination with extractive matter. The proportions of the astringent principle in barks vary considerably according to the age and size of the trees from which they are taken, and probably also according to the different seasons in which they are gathered. In every astringent bark the interior white part (that is, the part next to the wood) contains the largest quantity of tannin; the proportion of extractive matter is generally greatest in the middle and coloured part, but the epidermis seldom furnishes either tannin or extractive matter.

Two pieces of calf-skin, which weighed when dry 120 grains each, were tanned, one in the strongest infusion of Leicester willow bark, and the other in the strongest infusion of oak bark. The process was completed in both instances in less than a fortnight, when the weight of leather formed by the willow bark was found equal to 161 grains, and that by the oak bark to 164 grains.

In another experiment, two pieces, which weighed when dry 94 grains, were slowly tanned, one by the weak infusion of the willow, and the other in oak bark. The process was completed in about three months; and it was found that one piece of skin had gained in weight 14 grains and the other 16½ grains. This increase is proportionally much less than that which took place in the experiment on the process of quick tanning. The colour of the pieces of leather was deeper than that of the pieces which had been quickly tanned, and, to judge from the proportions of the residual liquors, more of the extractive matters of the bark had been combined with them.

The other vegetable infusions examined by Sir Humphrey Davy were those of the barks of elm and common willows, of sumach, Mirabola nuts, tea, and some other vegetables of known astringent qualities, the results of which are given in tabulated forms with those of Biggins and Cadet de Gassicourt.

General ob-
servations.

(786.) 5. *General observations.*—Sir Humphrey Davy was led to conclude from the foregoing experiments, that in all the different astringent infusions the tanning principle is possessed of the same general properties and powers of combination. That in the process of tanning, if the astringent infusion contain extractive and colouring matter, these, as well as tannin, enter into chemical combination with the skin: but that in no case is there any reason to believe that gallic acid is absorbed in this process. That hence the different qualities of leather, made with the same kind of skin, seem to depend very much upon the different quantities of extractive and colouring matter it contains; the leather prepared by means of infusion of galls being generally found harder and more liable to crack than that obtained from the infusions of bark. When a skin is very slowly tanned in weak solutions of the barks or of catechu, it combines with a considerable portion of extractive matter, and in these cases, though the increase of the weight of the skin is comparatively small, yet it is rendered perfectly insoluble in water, and is found soft, and, at the same time, strong.

The most essential inference, perhaps, deduced from this inquiry, is, that of all the astringent substances yet examined, the extract of catechu is that which contains the largest proportion of tannin, half a pound of this extract being found to produce the same effect in tanning as from 4 to 5 pounds of common oak bark.

Sir Humphrey Davy concludes his Paper by remarking, with respect to lime water and solutions of pearl-ash, which have been proposed for expediting and improving the process of tanning, that, as these two substances form compounds with tannin which are not decomposable by gelatine, it follows that their effects must be highly pernicious; and there is very little reason to suppose that any bodies will be found which, while they increase the solubility of tannin in water, will not likewise diminish its attraction for the skin.

Mechanica:
Processes.

Manufactures.

(787.) *Process of tanning.*—It is necessary to observe, before we describe these processes, that all tanned leather is technically classed and universally known under the two denominations *hides* and *skins*; the former being commonly applied to the larger animals, as bulls, oxen, cows, &c., which are chiefly intended for the soles of stout shoes and other purposes requiring very thick and solid leather: while the latter term is used for calves, seals, &c., which, being thinner and more flexible, are intended for the upper leather of shoes and boots, for saddles, harness, &c.

Common process of tanning. Butts or bucks.

The heaviest and stoutest of the bull and ox hides are generally selected to make what are technically called *butts* or *bucks*, and are manufactured in the following manner:

When the horns, &c., have been removed, the raw hides are laid in a heap for two or three days, and are then suspended on poles in a close room called a smoke-house, which is heated somewhat above the common temperature by a smothering fire: this occasions incipient putrefaction, which loosens the epidermis, and renders the hair and other extraneous matter easy of separation from the true skin. This is effected by extending the hide on a wooden horse or beam of a convex form, and scraping it with a large two-handled knife called a *fleshing knife*, which is bent to suit the convexity of the beam.

The hides are then immersed in a pit containing water slightly impregnated with sulphuric acid. This operation, which is called *raising*, by distending the pores and swelling the fibres, prepares the hide for the reception of the tannin, and renders it more susceptible of its action.

When the hides are sufficiently *raised*, they are removed into a pit, in which they are laid smooth with a stratum of oak bark, ground to a coarse powder, between each. The pit is then filled with the tanning lixivium, or ooze, prepared from oak bark and water; and the hides remain a month or six weeks without being moved. At the end of this time, the tanning principle being exhausted, the ooze and spent bark are taken out of the pit and the hides put in again, stratified with fresh bark, and covered with fresh ooze as before. Here they remain about three months, when the same process is repeated, at about the same interval, three several times or more, according to the strength of the lixivium and the substance of the hides. When sufficiently tanned they are taken out of the pit, hung up in a shed to dry gradually, and, being compressed with a steel instrument, and beaten smooth, to render them firm and dense, the operation is complete; and, having been numbered, weighed, and stamped by the Excise officer, to ascertain the amount and to mark the payment of the duty, (which will be noticed by and by,) they are ready for sale, and are termed *butts* or *bucks*. These form the thickest and most substantial sole-leather for very strong shoes, and are chiefly intended for exportation.

Dr. Macbride, of Dublin, in a Paper published in vol. lxviii. of the *Philosophical Transactions*, has recommended the use of lime-water instead of plain water in making the oozes, but it does not seem to have been adopted, and, from the result of Sir Humphrey Davy's experiments, it appears rather to be pernicious than useful in expediting and improving the process of tanning.

Crop hides. *Crop hides* are thus manufactured:—The horns having been removed, the hides are immersed in pits containing

a mixture of lime and water, where they remain three or four days, being occasionally moved up and down that each part may be uniformly exposed to the action of the lime-water. They are then taken out of the lime-pit, and the hair, and other extraneous matter, being scraped off on a wooden beam, as before described, they are washed in water to free them from the lime and filth adhering. They are now immersed in a weak ooze, and by degrees are removed into other pits, containing solutions gradually increasing in strength, during which time they are taken up and put down (technically termed *handling*) at least once in every day, that all parts of the hide may be acted upon by the tanning principle equally and uniformly. This is continued for about a month or six weeks, when they are put into other pits with stronger ooze and a small portion of ground bark; whence, as the tannin becomes exhausted, they are removed to others in regular succession, with fresh ooze and fresh bark, for two or three months.

At the end of this period the hides are put into larger vats, called *layers*, in which they are stratified, or laid smooth in a lixivium of greater strength, and with a larger quantity of ground bark between each fold. Here they remain about six weeks, when they are taken up and relaid in the same manner, with fresh bark and strong ooze, for two months. This process is repeated, with little variation, once, twice, or thrice, at the discretion of the manufacturer, till the hides are thoroughly tanned, when they are taken out of the pits, suspended on poles to dry, and, being compressed and smoothed, nearly in the manner before described, are called *crop-hides*, and form the principal part of the sole-leather which is used in England.

The process of tanning *skins* (calves', seals', &c.) is somewhat different from *hides*. They are continued in the lime-pits for ten or fifteen days; they are then depilated and washed in water, after which they are immersed in an infusion of pigeons' dung, called a *grainer*, having the property of an alkali. Here they remain for a week or ten days, according to the state of the atmosphere and other circumstances, during which time they are frequently *handled* and scraped on both sides upon a convex wooden beam. This scraping, or *working*, as it is termed, with the action of the *grainer*, helps to discharge all the lime, oil, and saponaceous matter, and renders the skin soft and pliant, fitted to imbibe the tanning principle. They are now removed into pits containing a weak solution of bark, where they undergo nearly the same process of handling, &c., as *crop-hides*, but they are seldom stratified in layers; and the time occupied in tanning them is usually from two to four months, according to their nature and substance. The skins are then dried and sold to the currier, who dresses and blacks them for the upper leathers of boots and shoes, for harness, and various other purposes.

The light and thin sort of cow-hides and horse-hides undergo nearly the same process in tanning as calf-skins, and are applied to similar uses.

(788.) Mr. John Burbridge published a Work, in the year 1825, termed *The Tanner's Key*, where he explains an improved process of tanning leather, which appears to possess considerable advantages over the common method. It would exceed our limits to give the detail of the process as described in that Work; we shall therefore content ourselves with making an extract of such parts as will afford the reader a clear idea of the general principles and nature of the operation. It appears that the

Mechanical Processes.

Burbridge's process.

Manufac-
tures.

time required to tan a hide is greatly shortened by this process. Mr. Burbridge states that he has a sample of five crop-hides which weighed when raw 477 pounds, and when tanned 295, being 56½ pounds above the standard, or half the raw weight. These hides averaged, therefore, 59 pounds each, and were tanned in 101 days, during a mild Winter, and sold at Leadenhall.

The author observes, that to derive all the practicable benefits from his system, the tan-yard should be provided with a roof and sides to fix in Winter and unfix in Summer, in order to embrace the sun's influence and escape frosts as may be required. Twelve taps of proper sizes are capable of working 24 pits, so as to produce 1500 hides annually, and so on for any larger number that may be required; consequently 24 pits will yield as much leather as 100 by the old method.

"Lime your hides," says Mr. Burbridge, "about a week, then unhair them and let them soak in a brook till next day, then flesh them, and afterwards wash off all the lime again in the brook for an hour or two. Hides will certainly thus be better prepared for immersion in weak liquors, after the lime is well washed away, for lime is no service after unhairing, but, on the contrary, is injurious in my opinion, which corresponds in this respect with that of Sir H. Davy, as appears in his *Lectures on Agricultural Chemistry*."

"When hides are thus prepared, or in the ordinary manner, immerse them as usual in tannin from four to five degrees, and continue handling them frequently; but, in a few days after their first immersion, shift them into rather stronger liquor, (from one to two degrees,) and continue this once or twice a week until the gluten of the hide is dead, or penetrated gradually through, which generally requires two months; during which time they must be handled as often as possible, and sometimes a little bark added in order to keep up the strength and encourage the natural appetites of the hides, which will be destroyed if they are suffered to lie longer in weaker liquors than they have once had, or if shifted into weaker liquors by mistake, which happens daily in common tan-yards."

"You must thus progressively proceed up to liquors of 15°, and sometimes, if necessary, up to 20°, and if the hides, after remaining three days in either of these strong liquors, have not imbibed or reduced the strength in any degree, it is a sure proof that they are quite tanned."

Thus far it appears that in the general character of the process Mr. Burbridge does not vary materially, except in recommending the utmost attention should be paid to the proper strength of the liquors, upon which he considers greatly to depend the time required for the operation, and weight, and quality of the leather; in fact, he reduces the Art to a system, as he observes: "If you throw hides into bark and water, shift them occasionally, and let them lie long enough, they must be turned into leather; but by the use of an instrument employed for this purpose, and proper attention to the strength of the liquors, you may make better leather in four or five months than by the old system in one year."

Mr. Burbridge recommends strongly the use of valonia during the last month of the process for heavy crops.

Suppose hides have been three months tanning, and well struck through, but the centre not quite like the exterior fibres, or perhaps a slight bist in the middle,

which generally defies and protracts the common tanner's utmost exertions, and often consumes many months to tan the centre like the exterior, which is absolutely requisite or it never can be good leather, or command the best prices: in such case Mr. Burbridge recommends the following remedy: "Take 200 pounds of valonia, after being ground in a bark-mill, and put it into a large vat with a coverlid. Heat a copper with 100 or 120 gallons of water, and when boiling pour it into the vat upon the valonia, and cover it to prevent evaporation. Then refill your copper with water, and, when it boils again, in about three hours, draw off the liquor from the vat, and (having previously handled your hides and placed them at the sides of the pit) pour it into the pit with the strongest bark-liquor to be well mixed together; which will not only materially increase the strength of the bark-liquor, but enable it to strike quite through the centre of the hides, adding weight, shortening time, and giving leather a good nutmeg-colour, so much preferred by curriers and shoemakers."

"These further general directions and remarks may be useful. Suspending hides in pits is a very excellent plan, because the tan penetrates quicker by having a free circulation, and there is much less labour in handling or shifting hides when suspended on poles; but hides ought never to be suspended until half tanned, when the centre may be finished quicker that way."

"Make new taps every alternate day or three times a week; put in six baskets of bark the first day, and pump all your taps half round; pump your best or last made tap half into the new one upon the six baskets of bark, half the second tap into the best, and half the third tap into the second, the fourth into the third, and so on all round, as is the common principle in old tan-yards, but avoid the use of plugs, which, although they may save labour, create a much greater evil by preventing the extraction of the strength and virtue of the bark."

Several patents have been taken out both in England and America for improvements in the Art of tanning, generally with a view of further shortening the time of the process. We have given below a description of such as have come into use and seem to deserve particular attention. There are, however, in addition to these, methods employed which are kept entirely secret by the tanners who make use of them, the men in such cases taking the oath of secrecy.

Within a few years many patents have been taken out for methods of expediting the tanning, the most important of which we now propose to mention.

(789.) Mr. Francis G. Spilsbury, of Warshall, Staffordshire, took out a patent, in the year 1823, for a method of obtaining a more rapid action of the tanning liquor by pressure. Oblong square frames are provided, with metal loops fastened round their edges. On one of these a skin or hide is stretched, after being limed, cleansed, and prepared in the usual manner for tanning. Over this hide another of the frames is placed, then a second hide is laid above it, and a third frame is put above that. The three frames are arranged so that the metal loops of each shall be opposite to those of the others; screw bolts are then put through those loops, and screwed up sufficiently tight to prevent any liquor from passing between the frames and the hides. The whole is then set up edgewise, and there being two short pipes furnished with cocks in the upper edge of the middle frame, a pipe, in which there is also a cock that

Mechanica.
Processes.

Spilsbury's
patent.

Man-
fac-
tures.

descends from a cistern holding tan-liquor, is fastened to one of these by a union joint; and another cock being placed near the bottom in the same frame to let off the liquor when required; this completes the whole apparatus.

The cock at the top, which communicates with the tan-cistern, being opened, and the other near it being also opened, while that at the bottom is shut, the tan-liquor will run down between the hides, and drive out the air at the other cock, which as soon as any liquor appears in it is shut; the tan-liquor will then distend the hides, and press outwards with a force depending on the height which the tan-cistern is elevated above the frames.

The consequence of this pressure is that the tan-liquor oozes through the pores of the hides, and appears at the outside like dew; and by bringing fresh portions to act continually on them, causes them to be tanned much more speedily than by the common method, in which the hides lie in the liquor after it has ceased to operate on them, and are only passed into fresh liquor at intervals by a tedious manual operation.

When the skins are sufficiently tanned, the tan-cock is closed and the liquor run off at the lower cock; the frames are then separated from the tan-pipe, and from each other, and the hides being removed and their edges pared off, which were nipped or compressed between the frames, are then to be dried and finished in the usual manner.

This method of tanning has attracted much attention, and it is stated that hides of sufficient thickness to require a year for tanning in the common method can be finished in this way in six weeks, and that some skins may be tanned by it in eight or nine days.

The theory of the process seems to promise well for quick performance, but we have been informed, by some gentlemen in the trade, that the skins are not tanned evenly by this method, but that spots are left which are less acted upon by the liquor than others, and that leather made in this way is not so durable as the common sort.

The quantity of the hides which must be pared when they come out of the frames must certainly diminish the value of the process, and especially when oblong square frames (such as are represented in the figure of the specification) are used, which not being of the natural shape of the hides, must cause more waste; this is certainly worth consideration, although the parts to be cut away are the least valuable of the hides.

Knowles and
Duesbury's
patent.

(790.) A patent was granted to Thomas John Knowles, Esq. of Trinity College, Oxford, and William Duesbury, of Ronsal, Derbyshire, for improvements in tanning. In this method the hides are suspended vertically in a covered air-tight vat; from which, after a sufficient quantity of tan-liquor is admitted so as to rise a little above the hides, the air is exhausted by an air-pump, which, extracting the air from the pores of the hide, causes them to imbibe the tan-liquor more rapidly and effectually.

The vat for this purpose must be somewhat deeper than the broadest hides, and its breadth must exceed a little their greatest length, while its length must be determined by the number of hides that are required to be suspended in it at the same time. Along the upper part of its opposite sides, hooks are fixed to support the hides by their upper angles, and in the middle of its top an aperture is made by which a man may go down to suspend the hides on the hooks, or to clean out the

vat; a cover is fitted into this aperture, round the edges of which leather is fastened, to prevent air from entering after it is fixed in its place. From the upper part of one side of the vat, a pipe furnished with a cock passes to an air-pump; from the top of the opposite side another pipe proceeds outwards a few inches, by which air may be admitted when required, and which likewise is closed by a stop-cock; and from the bottom of the vat a tube passes to the bottom of a pump, by which the tan-liquor may be drawn out after it is used. The patentees state that the vat may be made of any substance except iron, but it is not likely that any other material but wood will be employed in its fabrication.

When the vat is thus prepared the hides are to be suspended across it on hooks within small distances of each other, and lead weights are to be fastened to the bottom of each of the sides at regular intervals asunder, to keep them down evenly in their places; the tan-liquor is then to be run into the vats until it rises above the hides to within two or three inches of the top, and the cover is to be closed down over the main passage; after which the air-pump is to be worked until the air is sufficiently exhausted from the vat. In this state the whole is to be left for about twenty-four hours, after which the tan-liquor is to be pumped out, first opening the pipe for the admission of air, and then the vessel is to remain empty for two or three hours, to permit the hides to imbibe air again in their pores; and this process is to be repeated successively until the hides are sufficiently tanned. At first weak tanning liquor is to be used, and its strength is to be increased as the tanning of the hides advances. The patentees find it useful to put a little oil on the top of the liquor in the vat, to prevent bubbles issuing from it, so as to make the liquor run into the air-pipe when the air is being exhausted.

This method of tanning seems to be founded on very just principles, and to be likely to tan the hides completely, from its causing the tan-liquor to act equally on every part of them at the same time, while the exhaustion of the air as directed will, we should suppose, much accelerate the operation. We are not, however, acquainted with the precise ratio in which this process exceeds in rapidity that in common use.

(791.) A patent was granted to William Brown, of the City of New York, America, for a labour-saving tanning apparatus. The improvement consisted in connecting and concentrating various processes through which the hides pass before they become leather, by means of suitable apparatus, the construction of which is as follows:

For infusing the bark there are four or more leaches, or cisterns, which are placed contiguous to the handlers or vats on the same level, but projecting at the top above them. These leaches, or cisterns, communicate with each other by means of tubes, inserted between them near the tops, and are supplied with false bottoms, which fit loosely, and which are perforated with holes, forming a kind of strainer. In each of the leaches is fixed an aqueduct, or tube, which is used to convey the liquor from the bottom to the communicating tubes. By this contrivance the liquor is passed from the bottom of one leach into the top of the adjoining one, where it acquires a fresh portion of strength, and is thus propelled through the whole series, by pouring the water or weak liquor into the tops of the leaches, until, being of sufficient strength, it arrives at the fourth or strongest

Mechanical
Processes.

Manufac-
tures.

leach. There is also placed in one corner of each of these leaches what is called an eye, which consists of a trunk projecting below the bottom of the leach, and connected to a horizontal pipe, which serves to convey the liquor, when of sufficient strength, directly to the handlers or vats; this trunk is supplied with a plug for regulating the quantity of liquor thus drawn off.

At a convenient distance from the leaches, and on the same level with them, is placed a heater, which consists of two or more horizontal copper or iron pipes, placed one above the other, and having connecting tubes near their ends. These pipes are attached to and communicate with another of a square form, in which the fire is made, and they are secured within a cistern, with their ends projecting at one side, and have caps for the convenience of cleaning.

It will be seen that, when the fire is kindled in the lower heater or box, the heat passes from it into the tube above at its furthest extremity, and comes forward and enters the next above, and so goes backward and forward until it enters the chimney at the opposite side, thus transmitting all the heat of the fire to the liquor with which the cistern is constantly filled. There is a tube communicating with the heating cistern for supplying it with weak liquor or water, which communicates at its opposite extremity with a trunk or reservoir, furnished with a pump, by which the liquor is raised to the tube and forced into the heated cistern, which is kept constantly full by this means; the heated liquor passing off at a different tube, which communicates directly with the leaches. The leaches are filled with bark by means of a conveying trough communicating with the elevators of the mill. The strong liquor or infusion passes from the bottom of the leaches, as before mentioned, into a trunk, passing into a horizontal position under them, and rises by a vertical tube inserted in the said trunk, from which it is transmitted to another horizontal trunk communicating with the handlers or vats, passing along their upper surfaces. By this method the liquor from the leaches is transmitted into the tops of the handlers or vats. At the bottom of the vertical tube, and within the lower horizontal trunk, is placed a valve, movable by means of a strap extending up through the said tube, which is to prevent the stronger liquor from entering the reservoir, and thus mixing with the weaker.

The liquor, after having passed through the handlers or vats, is drawn from their taps by means of a hollow plug inserted into the lower trunk before mentioned, and runs into the trunk or cistern, whence it is again transmitted to the heaters, and so on to the leaches; so that the same liquor is continually in use, the evaporation and waste of which is supplied by water.

In each of the handlers is a reel or cylinder, formed by two circular heads, secured at the required distance apart by longitudinal bars, and having gudgeons which work in slides for the convenience of elevating or depressing them at pleasure. The hides are secured on the inside of the reels by means of hoops, which encircle the reels a short distance from their heads, and have pins on their outer surfaces by which the hides are fastened; or they may be thrown loose into the reels.

The great saving of labour in this invention consists in the facility with which the hides may be kept in motion when immersed in liquor. Each of the reels has a ratchet wheel attached to it, and is turned one

VOL. VII.

notch at a time, by means of a shaft, which is geared into a link, to be worked by hand, or may be moved by animal, water, or steam power. The piston of the pump in the trunk or reservoir is attached to one of the shafts, and may be moved or unshipped at pleasure.

There is what is called a beam-house connected with this apparatus, where the hides are first limed before they are put on reels. The water which is necessary to mix the lime is heated and supplied on the same principle as that before mentioned for the leaches; and the piston of the pump is attached in a similar manner to the shaft. In laying away hides it is necessary to have the ground bark which is put between them moistened or damped, to prevent waste and dust. The contrivance for this purpose consists of a small cistern, elevated at a convenient height, and supplied with a spout perforated with holes, and a cock for regulating the quantity of water required to wet the bark, which is placed under it. The patentee claims the privilege of using his improved labour-saving apparatus on as large or small a scale as he may require, and with any number of leaches and handlers.

(792.) The most recent patent for improvements in tanning of any importance was granted to Mr. William Drake, tanner, of Bristol, dated October 7, 1831. The nature of the invention consisted in causing tannin to enter the hides or skins by supplying cold tan liquor to one side, and evaporating by artificial heat from the other side a portion of the moisture which oozes through it, whereby the strongest portion of the tannin is left in the skin, while the strength of the liquor continually increases during the tanning process, instead of becoming weaker, as in the ordinary case of proceeding.

By this improved process the patentee states a hide or skin may be tanned in ten days as completely as would require ten months to perform by the usual method. The manner of conducting the process he thus describes:

The skins and hides intended to be tanned, after undergoing the usual processes of liming, &c., are immersed in a backward or weak tan liquor, with frequent and continued handling: they thus become saturated with liquor, and receive their preparatory colouring before their intended submission to the improved process. The skin is then to be carefully examined, and should any holes be found in it, they are to be sewed up, or otherwise stopped, in order to prevent the liquor with which they are intended to be filled from escaping, except through the pores of the hide.

Should it be intended to tan the hides as butts, middlings, or any other shape than the natural one, the intended shape must be given at this part of the process, by rounding or cutting off the extraneous parts.

Some other patents for improvements in tanning, both English and American, might be enumerated, which our limits will not permit us to describe, and we beg to refer the reader to the *Repertory of Arts*, where all deserving of notice are given either in the words of the specification, or in such a description as will perfectly explain the views of the inventor.

Tawing, Currying, Leather-dressing, &c.

(793.) The dressing and preparation of the skins of lambs, sheep, goats, and other thin hides, although in many particulars closely resembling the methods we have described, forms usually a totally distinct branch of

Mechanica
Processes.

Tawing,
currying
&c.

Manufac-
tures.

business, and is one in which a good deal of practical skill and nicety of manipulation are required to succeed perfectly: we are indebted for the following account of these processes to Aikin's *Chemical Dictionary*.

The processes are very various, according to the article required, and this branch of the manufacture supplies the immense demand of white and dyed leather for gloves; that termed Morocco leather, of different colours and qualities, for coach-lining, bookbinding, pocket-books, &c.; and thin leather for an infinite number of smaller purposes. Of these, the white leather alone is not tanned, but finished by the process of tawing; but the coloured leather always receives a tanning (generally by sumach) independently of the other dyeing materials. The previous preparation of each, or that in which the skin is thoroughly cleansed and reduced to the state of simple membrane, in which it is called *pelt*, is essentially the same whether for tawing or dyeing. It is thus performed at the best manufactories at Bermondsey, near London, a place long celebrated for all branches of the leather business.

Lamb-skins.

Lamb-skins are prepared by first soaking them for a time in water to remove any loose dirt and blood, and then placing them upon a beam composed of a half cylinder of wood covered with strong leather, and scraped on the flesh side with the semicircular blunt knife, commonly used in this operation. They are then hung up in considerable numbers in a small close room heated by flues, where they remain to putrefy for a given time. During this process a thick filthy slime works up to the surface of the skin, by which the regularity of the process is judged of, and the wool is loosened so that it readily comes off with a slight pull. Each skin is then returned to the beam, the wool taken off and preserved, and all the slime worked off with the knife, and the rough edges pared away. The skin is then put into a pit filled with lime-water, and kept there from two to six weeks, the time depending upon the nature of the skin: this has the effect of checking the further putrefaction, and produces a very remarkable hardening and thickening of its substance, and probably, also, it detaches a further portion of the slime. The skin is again well worked upon the beam, and much of its substance pared down, and all inequalities smoothed with the knife. Much care and judgment are required in these operations; on the one hand not to endanger the substance of the skin by the putrefaction, which, if carried on too long, would soon reduce it to an incohesive pulp; and on the other hand to work out every particle of the lime, the least of which, if retained, will prevent the skin from dressing well in the subsequent processes, and from taking the dye uniformly.

The skin is then again softened by being thrown into a vat of bran and water, and kept there for some weeks in a state of gentle fermentation, being occasionally returned to the beam. All the thickening produced by the lime is thus removed, and the skin is now as highly purified as possible, and becomes a thin extensible white membrane, called in this state the *pelt*, and is now fit for any subsequent operation of tawing, dyeing, oil-dressing, or shammying.

Kid and
goat skins.

The method of bringing kid and goat skins in the state of *pelt* is nearly the same as for lambs, except that the liming is used before the hair is taken off, the hair being of no great importance, and sold only to plasterers, but the lamb's wool, which is more valuable, would be injured by the lime.

If the pelts are to be tawed, they are then put into a solution of alum and salt in warm water, in the proportion of about 3 pounds of alum and 4 pounds of salt to every 120 middle-sized skins, and worked about in it till they have absorbed a sufficient quantity. This again gives the skin a remarkable degree of thickness and toughness. The skins are then taken out and washed in water, and then again put into a vat of bran and water, and allowed to ferment for a time, till much of the alum and salt is got out, and the unusual thickness produced by it is for the most part reduced. They are then taken to a lofty room with a stove in the middle, and stretched on hooks, and kept there till fully dry, when they become tough and flexible, and quite white leather; but to give them a glossy finish, and to take off the harshness of feel still remaining, they are again soaked in water to extract more of the salt, and put into a large pail containing the yolks of eggs beat up with water. Here the skins are sodden for a long time, by which they so completely imbibe the substance of the egg that the liquor above them is rendered almost limpid; after which they are hung up in a loft to dry, and finished by glossing with a warm iron, which completes the operation.

The essential difference, therefore, between tanning and tawing is, that in the former case the pelt is combined with tan and other vegetable matter, and in the latter with something that it imbibes from the alum and salt, (probably alumine,) and which certainly is never again extracted by the subsequent washing and branning.

(794.) *English Morocco leather*.—The leather called English Morocco leather, which is chiefly prepared from sheepskins, and used so largely for coach-lining, pocket-books, and the best kind of bookbinding, is thus made. The skin, cleansed and worked in the way already described, is taken from the lime-water, and the thickening thereby occasioned is brought down, not by bran liquor, as in tawing, but by a bath of dog's or pigeon's dung, diffused in water, where it remains till sufficiently supplied, and till the lime is quite got out, and it becomes a perfectly clean white pelt. If intended to be dyed red, it is sewed up very tight in the form of a sack with the grain side outwards, (the dye being required only on this side,) and is immersed in a cochineal bath of a warmth just equal to that which the hand will bear, and is worked about until it is uniformly dyed, a process that demands much skill and experience. The sack is then put into a large vat, containing sumach infused in warm water, and kept for some hours until sufficiently tanned. The skins intended to be blacked are merely sumached, without any previous dyeing.

After some further preparation, the colour of the fine red skins being finished with a weak bath of saffron, the skins, when dried, are grained and polished in the following manner. They are stretched very tight upon a smooth inclined board, and rubbed over with a little oil to render them supple. Those intended for black leather are previously rubbed over with an iron liquor, by means of a stiff brush, which, uniting with the gallic acid of the sumach, instantly strikes a deep and uniform black.

They are then rubbed by hand with a ball of glass cut into a polygonal figure, which polishes them, and makes them very firm and compact. Lastly, the graining or ribbed surface, by which this kind of leather is distinguished, is given by rubbing the leather very strongly with a ball of box-wood, round the centre

and po-
lishing.

Manufac-
tures.

of which a number of small equidistant parallel grooves are cut, forming an equal number of narrow ridges, the friction of which gives the leather the desired inequality of surface.

Currying
leather.

(759.) *Currying leather*.—The common mode of currying leather for shoes, boots, &c., consists in first softening the hides, as they come from the tan-pit, by soaking them thoroughly in water; they are then placed on a polished beam with the flesh side outwards, and pared with a broad sharp knife, till all the inequalities are removed and it is reduced to the required thinness. They are then again rubbed and washed with a polished stone, and, while still wet, are besmeared with currier's oil, generally fish oil, or a mixture of this with tallow, which renders them much more impervious to moisture, and proper to protect the feet against the inclemency of the weather. They are afterwards hung up to dry, by which the moisture is evaporated, but the oil, which cannot be dissipated by mere exposure, gradually takes the place of the moisture, and penetrates deeply into the pores of the leather. It is then dried either in the sun or in a stoved room.

Blackening the leather is also a part of the currier's business, which is done on the grain side simply by rubbing it with an iron liquor, but on the flesh side with a mixture of lamp-black and oil.

Common boot leather, as usually prepared, is, however, still, in some degree, pervious to water, by long exposure to wet, and for this reason fishermen, wild-fowl shooters, and those whose employment or amusement leads them to be long on wet ground, usually prepare their boots with an additional dressing of some oily or viscous matter.

Shammoyed leather.—This is generally prepared from sheep or does' skin prepared in the way already mentioned by dressing, liming, &c., and dyed if necessary, and then finished with oil. This forms the common wash leather, breeches leather, &c., and is the only kind which, when dyed, will bear washing without the colouring being materially injured.

We add the following particulars relative to the manufacture of some of the most remarkable kinds of leather prepared in foreign Countries, which, although in most respects closely resembling ours, have distinct points of difference, which will be interesting both to the English manufacturer as well as to the general reader.

Real Mo-
rocco lea-
ther.

(796.) *Real Morocco leather*.—The process for the preparation of this leather from the goat-skins at Fez and Tetuan is thus described by M. Broussonet:—The skins are first cleansed, the hair is taken off, limed, and reduced with bran, nearly in the way already described for the English Morocco leather. After coming from the bran they are thrown into a second bath made of white figs, mixed with water, which is thereby rendered fermentable, in which they remain four or five days, and they are then thoroughly salted with salgum (or rock-salt) alone, in lieu of the salt and alum; after which they are fit to receive the dye, which, for the red, is cochineal and alum, and for the yellow pomegranate-bark and alum; the skins are then tanned, supplied with a little oil, and dressed.

Russia leather.—Much excellent leather of every kind is prepared in different parts of the Russian Empire. The preparation of the fine Russian leather, so well known for its quality and for its peculiar smell, is described at large in Mr. Tooke's *View of the Russian*

Empire, to which we must refer the reader for the minutiae of the processes. The hides are first put into a weak alkaline ley to loosen the hair, and then scraped on a beam; then (if calves) are reduced by dog's dung and a sour oatmeal drench, and tanned with great care and frequent handling; the bark used here is seldom oak, that of the black willow being preferred; but if this cannot be obtained, they use the birch bark. They are then either dyed red or black, these being the two colours most esteemed. For the red the hide is first soaked in alum, and then dyed with Brazil wood, and the black is given as usual with an iron liquor. The leather is then smeared with birch bark, which gives the peculiar smell so much prized, and which, when used for bookbinding, has the valuable property of protecting the book from worms. The streaked or barred surface is given to the leather by a very heavy steel cylinder wound round with wires.

A valuable Saffian or dyed Maroquin leather, almost equal to that of Turkey, is prepared at Astracan and in other parts of Asiatic Russia. Buck and goat skins are the only ones used for this purpose, and the favourite colours are red and yellow. The general method of preparing the pelt is the same as used in this Country for the dyed Morocco leather; that is, by lime, dog's dung, and bran. Honey also is used after the branning; it is dissolved in warm water, and some of the liquor poured on each skin, spread out on wooden trays, till it has imbibed the whole of the honey, after which it is permitted to ferment for about three days, and then salted in a strong brine and hung up to dry. The skin is then ready to receive the dye, which for red is made with cochineal and the *Salsola ericoides*, an alkaline plant growing plentifully on the Tartarian salt deserts, and the colour is finished with alum. When dried, the skins are generally tanned with sumach, but for the very finest reds a quantity of sorrel is used with the cochineal bath, and the subsequent tanning is given with galls instead of sumach, which render the colour as durable as the leather itself. The roughness always observed on the surface of the skin is given by a heavy kind of iron rake with blunt points. The yellow Saffians are dyed with the berries of a species of *rhamnus*, (the Avignon berry would answer the same purpose, and is used in other Countries,) or with the flowers of the wild camomile.

(797.) *Shagreen leather*.—This singular and valuable leather is a manufacture almost peculiar to Astracan, where it is prepared by the Tartars and Armenians. For making shagreen only horses' or asses' hides are taken; and it is only a small part, from the crupper along the back, that can be used for this purpose, which is cut off immediately above the tail in a semicircular form, about 34 inches upon the crupper, and 28 along the back. These pieces are first soaked in water till the hair is loose and can be scraped off, and the skin, after being again soaked, is scraped so thin as not to exceed a wetted hog's bladder in thickness, and till all the extraneous matter is got out, and only a clean membranous pelt remains. The piece is then stretched tight on a frame, and kept occasionally wetted, that no part may shrink unequally. The frames are then laid on a floor with the flesh side of the skin undermost, and the grain side is strewed over with the smooth black hard seeds of the *Ala lenta* or goose foot, (*Chenopodium album*), and a felt is then laid upon them, and the seed trodden deeply into the soft moist skin, which gives the peculiar mottled surface

Mechanical
Processes.

Shagreen
leather.

Manufac-
tures.

for which shagreen is distinguished. The frames, with the seeds still sticking to the skin, are then dried slowly in the shade, till the seeds will shake off without any violence, and the skin is left a hard horny substance with the grain side deeply indented. It is then laid on a solid block covered with wool, and strongly rasped with two or three iron instruments, till the whole of the grain side is shaved, so that the impression of the seeds is very slight and uniform; the skins are then softened first with water, and then with a warm alkaline ley, and are heaped warm and wet on each other, by which means the parts indented by the impression regain much of their elasticity, and, having lost none of their substance by paring, rise up fully to the level of the shaved places, and thus form the grain or granular texture peculiar to the shagreen. The skin is then salted and dyed.

The beautiful green colour is given by soaking the inner or flesh side of the skin with a saturated solution of sal ammoniac, strewing it over with copper filings, rolling it up with the flesh side inwards, and pressing each skin with a considerable weight for about 24 hours, in which time the sal ammoniac absorbs enough of the copper to penetrate the skin with an equable sea-green colour. This is repeated a second time to give the colour more body. Blue shagreen is dyed with indigo, dis-

solved in an impure soda by means of lime and honey. Mechanical Black shagreen is dyed with galls and vitriol; they are Processes. in each case finished with oil or suet.

We conclude this section with the following Tables of the amount of duty on hides and skins, quantities imported and exported, &c. &c., from 1820 to 1831 inclusive.

(798.) *Quantities of Goats' Skins, Horse and Cow Hides, tanned, tawed, and dressed in Oil, charged with Duties of Excise, and Net Produce of Duties in each Year, from 1820 to 1831, both inclusive:—*

Years.	Pounds of Hides and Skins.	Amount of Duty.

WORKS OF PUBLIC AND DOMESTIC UTILITY.

*Gas Works.*Gas Works
their im-
portance.

(802.) Next to the application of steam power to navigation, the discovery of the illuminating power of gas at a distance from its point of generation is the most important and interesting made in modern times; and will claim therefore particular attention. A very little more than one hundred years back, the streets of London were in the night involved in almost total darkness. At that time, the inhabitants in the larger streets were, by the Lord Mayor, ordered to hang out lanterns, giving just sufficient light to render the darkness more visible, and even these were all extinguished at about eleven o'clock. After this, the system of glass lamps furnished with oil began to be more generally adopted, not only in London, but in the larger towns in the Country, and Acts of Parliament were granted to different parishes, authorizing the overseers or commissioners to defray the expense of the same by a general rate. The lights, however, were still very sparingly distributed, with single wicks, miserable in appearance and nearly useless in effect. Afterwards, the wick was enlarged, double and triple lights were introduced, and the number greatly multiplied, so that something like a night illumination was produced; still great indeed was the step from this best mode of lighting with oil, and that which is now obtained by gas, which has made the streets of London, and of all the larger and indeed the minor towns in the Kingdom, nearly as light by night as by day.

We have above spoken of this as the discovery of the means of illuminating by gas at a distance from its point of generation, and it is in this, and not in the illumination itself, that the discovery consists; for a little consideration will show us that these very gases have at all times been the real materials from which artificial light has been obtained. The light from a blazing coal fire, what is it but the result of the combustion of coal-gas? while that from a burning lamp or candle is nothing more than the combustion of oil-gas. The essential difference between gas light and that from other combustible substances is merely in the manipulation or process, and the interposition of an interval between the production of the gas and the consumption of it. This will be evident if we attend to the succession of events which take place during the burning of a common candle. The solid oil is first melted by the heat of the flame, the fluid then rises up the wick by capillary attraction, gets more and more hot as it approaches the flame, till it has acquired a temperature capable of destroying that particular mode of combination of its elements which forms oil, and of producing therefrom new compounds, one or two of which are inflammable gases. These gases, in proportion as they are formed, take fire and burn with flame, because, at the very instant of their formation, they are both at a high temperature and in contact with atmospheric air. Now, if the oil, while decomposing, is excluded from the air, combustion will not take place; and the inflammable gases resulting from the decomposition of the oil may be collected by a proper apparatus and stored up for future use. So, in the same manner, if a piece of coal is laid upon a clear burning fire, it soon acquires a temperature sufficient for its decomposition, several inflammable gases are produced which burn in jets of white light as they issue from the coal into the air, or may be collected without

undergoing combustion by an apparatus that shall exclude the air. Mechanical Processes.

The only very obvious way of so decomposing oil or coal, that the inflammable products of such decomposition shall not be burned, is by heating them in close vessels; but in so doing, not only inflammable gas is produced, but so also are various other substances which do not make their appearance when oil or coal is burned in the open air. These substances detract from the purity of the gas, diminishing its combustibility, or occasioning a disagreeable odour, and therefore render it necessary to have recourse to various processes in order to separate them from the gas before it is made use of.

Thus, it appears, the manufacture of gas for illumination requires the use of close vessels, and likewise of some process of purification, and it is the construction of such vessels, and the methods of applying them to the purposes in question, which necessarily constitute the elements of this invention.

(803.) *History of lighting by coal gas.*—Notwithstanding the very recent adoption of this beautiful invention, some doubt exists as to the person to whom the honour of the discovery is due; indeed this, like most other important inventions, has been occasionally touched upon, and isolated properties brought to light, which for want of connection have been suffered to fall again into oblivion, till at length, when the connection is discovered, one puts in a claim for some particular author or experimenter, and another for a second, and so on, till at length the statement, instead of being clear and intelligible, is complicated and confused by claims, many of which have a very remote connection, if any, with the subject under discussion. This is the case with the history of gas lighting; we hope, however, the following brief statement will point out most of the principal steps without prejudice or partiality. History of gas lighting.

In the first place it may be observed, that the history of this discovery or invention may be divided into two branches: viz. the discovery of the inflammability of the gas obtained from coal, and, secondly, the invention of proper means of separating this gas from the other component parts, and applying it to useful purposes of utility and economy.

(804.) That coal contained such a gas has been known for many years, probably long before we have any record of such observations, but even these may be traced back as far as the year 1667, when Thomas Shirley, Esq., communicated to the Royal Society an account of a well and earth in Lancashire taking fire on the approach of a candle. This account, which is very short, may be interesting to the reader; we give it in the author's own words: Coal gas first described, in 1667, by Shirley.

"About the latter end of February, 1659, returning from a journey to my house in Wigan, I was entertained with the relation of an odd spring situated in one Mr. Hawkley's grounds, (if I mistake not,) about a mile from the town, in that road which leads to Warrington and Chester.

"The people of this town did affirm, that the water of this spring did burn like oyle; into which error they suffered themselves to fall for want of due examination of the following particulars:

"For when I came to the said spring, (being five or six in company together,) and applied a lighted candle to the surface of the water, 'tis true there was suddenly a large flame produced which burnt vigorously; at the sight of which they began to laugh at me for denying what they had positively asserted. But I, who did not

Manufac-
tures.

think myself confuted by laughter grounded upon inadvertency, began to examine what I saw; and observing that this spring had its eruption at the foot of a tree growing on the top of a neighbouring bank, the water of which filled a ditch that was there, and covered the burning place lately mentioned; I then applied a lighted candle to divers parts of the water contained in the said ditch, and found, as I expected, that upon a touch of the candle and the water the flame was extinct.

"Again having taken up a dish full of water at the flaming place, and held the lighted candle to it, it went out. Yet I observed that the water at the burning place did boyle, and heave like water in a pot upon the fire, though my hand put into it perceived it not so much as warm.

"This boiling I conceived to proceed from the eruption of some bituminous or sulphureous fumes, considering this place was not above thirty or forty yards distant from the mouth of a coal-pit there. And indeed Wigan, Ashton, and the whole country for many miles' compass, is underlaid with coal. Then, applying my hand to the surface of the burning place of the water, I found a strong breath, as it were a wind, to bear against my hand.

"Then I caused a dam to be made, and thereby hindering the recourse of fresh water to the burning place, I caused that which was already there to be drained away; and then applying the burning candle to the surface of the dry earth at the same point where the water burned before, the fumes took fire and burned very bright and vigorous. The cone of the flame ascended a foot and a half from the superficies of the earth. The basis of it was the compass of a man's hat about the brim. I then caused a bucket full of water to be poured on the fire, by which it was presently quenched, as well as my companions' laughter was stopped, who began to think the water did not burn.

"I did not perceive the flame to be discoloured, like that of sulphureous bodies, nor to have any manifest scent with it. The fumes when they broke out of the earth, and prest against my hand, were not, to my best remembrance, at all hot."

There can be little doubt but that the "bright and vigorous flame" which the writer describes proceeded from what we now call carburetted hydrogen gas.

Another communication relative to the inflammability of coal gas was made to the Royal Society in 1733, by Sir James Lowther; and another by Dr. Clayton, in 1739, but which, from other circumstances, appears to have been written some years before, being an extract from a letter without date, addressed to Mr. Boyle, who died in 1691. The following extracts from these Papers are highly interesting, and, being intimately connected with the present subject, we make no apologies for placing them before our readers, as they are given in the *Abridgment of the Philosophical Transactions* by Dr. Hutton.

Spontaneous
combustion,
1733.

(805.) "Sir James Lowther having occasion to sink a pit very near the full sea-mark, for draining one of his principal collieries near Whitehaven, in the County of Cumberland, which it was known would be near eighty fathoms in depth to the best seam of coals, which is three yards thick, the work was carried on day and night very successfully, through several beds of hard stone, coal, and other minerals, till the pit was sunk down forty-two fathoms from the surface, where they came to a bed of black stone about six inches thick, very full of joists, or open clefts, which divided the stones into pieces

of six inches square, the sides being all spangled with sulphur, and in colour like gold. Under this black stone lies a bed of coal two feet thick. When the workmen first pricked the black stone bed, which was on the rise side of the pit, it afforded very little water, contrary to what was expected; but instead of it a vast quantity of damp corrupted air, which bubbled through a quantity of water, then spread over that part of the pit, and made a great hissing noise; at which the workmen being somewhat surprised held a candle towards it, and it immediately took fire on the surface of the water, and burned very fiercely, the flame being about half a yard in diameter and near two yards high, which frightened the workmen, so that they took the rope and went up the pit, having first extinguished the flame, by beating it out with their hats. The steward of the Works, being informed of it, went down the pit with one of the men, and, holding a candle to the same place, it immediately took fire again, as before, and burnt about the same size, the flame being blue at the bottom and more white towards the top. They suffered it to burn near half an hour, and no water being drawn in that time, it rose and covered the bottom of the pit near a yard deep, but that very little abated the violence or bulk of the flame, it still continuing to burn on the surface of the water. They then extinguished the flame as before, and opened the black stone bed near two feet broad, that a greater quantity of air might issue forth, and then fired it again; it burned a full yard in diameter, and about three yards high, which soon heated the pit to so great a degree, that the men were in danger of being stifled, and so were as expeditious as possible in extinguishing the flame, which was then too strong to be beaten out with their hats; but with the assistance of a spout of water, of four inches diameter, let down from a cistern above, they happily got it extinguished without further harm. After this, no candles were suffered to come near it, till the pit was sunk down quite through the bed of black stone, and the two feet coal underneath it, and all that part of the pit, for four or five feet high, was framed quite round, and very close jointed, so as to repel the damp air, which nevertheless, it was apprehended, would break out in some other adjoining part, unless it was carried quite off as soon as produced out of the clefts of the stone, for which end, a small hollow was left behind the framing, to collect all the damp air into one side of the pit, where a tube of about two inches square was closely fixed, one end of it in the hollow behind the framing, and the other carried up into the open air, four yards above the top of the pit; and through this tube the said damp air has ever since discharged itself, without being sensibly diminished in its strength, or lessened in its quantity, since it was first opened, which was two years and nine months before. It is just the same in Summer as in Winter, and will fill a large bladder in a few seconds, by placing a funnel at the top of the tube, with the small end of it put into the neck of the bladder, and kept close with one's hand.

"The air, thus enclosed in the bladder and tied close, may be carried away and kept some days, and, being afterwards pressed gently through a small pipe into the flame of a candle, will take fire and burn at the end of the pipe as long as the bladder is gently pressed to feed the flame; and when taken from the candle, after it is so lighted, it will continue burning till there is no more air left in the bladder to supply the flame.

"The air when it comes out at the top of the tube is

Mechanical
Processes.

Manufactures.

as cold as frosty air. It is to be observed that this sort of vapour, or damp air, will not take fire except by flame; sparks do not affect it, and for that reason it is frequent to use flint and steel in places affected with this sort of damp, which will give a glimmering light, that is a great help to the workmen in difficult cases.

"After the damp air was carried up in a tube, in the manner above described, the pit was no more annoyed with it, but was sunk down very successfully through the several beds of stone and coal, without any other accident or interruption, till it came to the main seam of coals, which is 3 yards thick, and 79 fathoms deep from the surface; and the said pit being oval, viz. 10 feet one way and 8 the other, it serves both for draining the water by a fire engine, and also for raising the coals."

Dr. Clayton's discovery, communicated 1739.

(806.) *Dr. Clayton's Memoir, from the Abridgment of the Philosophical Transactions, 1739.*—"Mention is here made of a ditch, two miles from Wigan in Lancashire, the water in which would seemingly burn like brandy, the flame being so fierce that several strangers boiled eggs over it; the neighbouring people indeed affirmed, that about thirty years before it would have boiled a piece of beef; and that whereas much rain formerly made it burn much fiercer, now after rain it would scarcely burn at all. It was after a long-continued season of rain that Dr. C. went to see the place and make some experiments, when he found that a lighted paper, though it were waved all over the ditch, would not set the water on fire. He then had a dam made in the ditch, and the water thrown out, to try whether the steam which arose from the ditch would then take fire, but he found it would not. He still, however, pursued his experiment, and caused it to be dug deeper; when at the depth of about half a yard he found a shelly coal, and the candle being then put down into the hole, the air caught fire and continued burning.

"Dr. C. observed that there had formerly been coal pits in the same close of ground; and, having got some coal from one of the nearest pits, he distilled it in a retort in an open fire. At first there came over only phlegm, afterward a black oil, and then also a spirit arose, which he could no ways condense, but it forced the luting or broke the glasses. On one occasion when it had forced the lute, coming close to it, to try to repair it, he observed that the spirit which issued out caught fire at the flame of the candle, and continued burning with violence as it issued out in a stream, which he blew out and lighted again, alternately, for several times. He then tried to save some of this spirit; taking a turbinated receiver, and putting a candle to the pipe of the receiver while the spirit rose, he observed that it caught flame, and continued burning at the end of the pipe, though you could not discern what fed the flame; he then blew it out, and lighted it again several times, after which he fitted a bladder, flatted and void of air, to the pipe of the receiver. The oil and phlegm descended into the receiver, but the spirit still ascended and blew up the bladder. He then filled a good many bladders with it, and might have filled an inconceivable number more, for the spirit continued to rise for several hours, and filled the bladders almost as fast as a man could have blown them with his mouth; and yet the quantity of coals he distilled was inconsiderable.

"He kept this spirit in the bladders a considerable time, and endeavoured several ways to condense it, but in vain. And when he wished to amuse his friends, he would take one of these bladders and, pricking a hole

with a pin, and compressing gently the bladder near the flame of a candle till it once took fire, it would then continue flaming till all the spirit was compressed out of the bladder.

"But then he found that this spirit must be kept in good thick bladders, as in those of an ox, or the like; for if he filled calves' bladders with it, it would lose its inflammability in twenty-four hours, though the bladder became not at all relaxed."

(807.) Another communication was made to the Royal Society by Dr. Brownrigg in 1746, in which was described a method he had adopted in his laboratory for procuring a perpetual flame for chemical uses, by conveying from an adjacent coal pit a constant stream of inflammable gas through a leaden pipe. This was not, however, published for more than twenty years after, the author having had in view at the time a large Work on Chemistry, and at his request the communication was not published in the *Transactions*.

(808.) Notwithstanding this contrivance, it may be said that up to this time the discoveries that had been made were rather accidental than as results drawn from scientific views and investigations. But in 1767 Dr. Watson, afterwards Bishop of Landaff, undertook an examination of the properties of the component parts of coal, and he published the result of his researches in the second volume of his *Chemical Essays*. His experiments show that he examined the products arising from the distillation of pit coal with great care; and he has described them with his usual exactness. In his process he permitted the gas to ascend through curved tubes, and he particularly notices its great inflammability, as well as elasticity; he also observed, that it retained the former property after it had passed through a great quantity of water. After detailing a variety of interesting facts and calculations, respecting the quantities of coke, tar, &c., produced from various kinds of coal, he gave several useful queries to excite others to investigate the subject with a view to further discoveries. From his habit of acute and vigilant observation, and his general endeavours to render his experiments subservient to utility in the Arts, it may, perhaps, excite some surprise that the uses to which the inflammability of the coal gas was applicable should not have suggested themselves to his penetrating mind. But as the voyager, when in the search of unknown regions, has often approached very near to an interesting point, without having had the felicity to discover it; so has it occurred to the scientific explorer of nature in his diversified excursions among her unfrequented recesses. Indeed, how numerous are the discoveries which have resulted from experiments made rather with a view to private amusement than in the serious pursuit of any important object! Yet many of these have occasionally been productive of momentous consequences to mankind; and how remarkably has this proved to be the case with regard to the uses and application of coal gas!—Matthews's *History*.

(809.) Soon after this time, the late Earl of Dundonald took out a patent for distilling coals, and obtained therefrom coke and tar, the process in all its essential particulars being the same that had been largely practised at Liege, about the year 1740. Lord Dundonald's plan was for a time carried on very extensively at Colebrook Dale in Shropshire, and remnants of his Works were to be seen there some years back. The collection and employment of the gas produced by the distillation of the coal formed no part of the patentee's plan; the gas, therefore, was

Mechanical Processes.

Earl of Dundonald's patent for distilling coal.

Manufac-
tures.

suffered to escape into the air, and sometimes from curiosity, and sometimes to avoid the stench of the gas, it was set fire to as it issued from the waste pipe of the apparatus.

Up to this period, therefore, no attempts appear to have been made to apply the inflammable gas from coal to the purposes of artificial illumination as a substitute for candles, or for oil lamps, and it is here, therefore, that commences the second period of the history, when means were devised for applying the gas to purposes of utility.

Artificial
gas light
ing at-
tempted by
Murdoch
in 1792.

(810.) In 1792 Mr. Murdoch, being then resident at Redruth in Cornwall, instituted a series of experiments on coal, the object of which was, to apply the inflammable gas, obtainable from this substance by distillation, to economical purposes. The apparatus employed by him on this occasion consisted of an iron retort, with metallic tubes turned on the inside, through which the gas was conveyed to a considerable distance. At the end of the pipe, and in various intermediate places, were perforations of different sizes and forms, where the gas was set fire to. He also made trial of different kinds of coal for the purpose of ascertaining which gave the greatest quantity of gas, and of the best quality. He likewise attempted to purify the gas by washing it in water, and by other means.

Soho manufac-
tory illu-
minated in
1802.

In the year 1798, he removed from Cornwall to Messrs. Boulton and Watt's foundry at Soho near Birmingham; where he resumed his experiments on a larger scale, having for many successive nights lighted the principal building in this establishment with coal gas, and practised various new methods of purifying it; and, in 1802, the whole front of the Soho manufactory was brilliantly illuminated with coal gas on account of the General Peace.

With these well-established facts before us, it seems impossible to deny to Mr. Murdoch the principal merit of the invention. It is certain that Dr. Clayton, fifty years before Mr. Murdoch, had proved the inflammable nature of the gas, and the same fact was known from the experiments of Lord Dundonald; but in the hands of one it was only an interesting philosophical experiment, and in the other a casual result of other experiments, and although it ought, perhaps, it does not appear to have suggested the idea of applying the gas thus produced to the economical purposes of illumination.

Great
progress in
the Art,
1808.
Mr. Mur-
doch re-
ceives the
Rumford
medal,
Royal So-
ciety, 1809.

Between the term at which we have now arrived, 1802 and 1808, great progress was made in the application of gas by Mr. Murdoch and others, which will be referred to as we proceed, but we think this the best place for introducing an abstract from Mr. Murdoch's Paper, presented in the latter year to the Royal Society, in which the successive steps of his proceedings are clearly and distinctly detailed, particularly with reference to the lighting of Mr. Lee's manufactory, which was first commenced in 1805. The author states, as we have before done, that at the time of making the communication sixteen years had elapsed since, in a course of experiments he was making at Redruth in Cornwall, upon the quantity and quality of gases produced by distillation from different minerals and vegetable substances, he was induced, by some observations he had previously made upon the burning of coal, to try the combustible properties of the gases produced from it, as well as from peat, wood, and other inflammable substances, and being struck with the great quantities of gas they afforded, as well as with the brilliancy of the light and the facility of its production, he instituted several experiments with

a view of ascertaining the cost at which it might be obtained, compared with that of equal quantities of light yielded by oils and tallow.

Mechanical
Processes.

"My apparatus," the author observes, "consisted of an iron retort, with tinned copper and iron tubes, through which the gas was conducted to a considerable distance; and there, as well as at intermediate points, was burned through apertures of varied forms and dimensions. The experiments were made upon coal of different qualities, which I procured from distant parts of the Kingdom, for the purpose of ascertaining which would give the most economical results. The gas was also washed with water, and other means were employed to purify it.

Abstract
from Mr.
Murdoch's
Memoir.

"In the year 1798, I removed from Cornwall to Messrs. Boulton, Watt, and Co.'s Works for the manufactory of Steam Engines, at the Soho foundry, and there I constructed an apparatus upon a larger scale, which, during many successive nights, was applied to the lighting of their principal building, and various new methods were practised of washing and purifying the gas.

"These experiments were continued, with some interruptions, until the Peace of 1802, when a public display of this light was made by me in the illumination of Mr. Boulton's manufactory at Soho, upon that occasion.

"Since that period, I have, under the sanction of Messrs. Boulton, Watt, and Co., extended the apparatus at Soho foundry, so as to give light to all the principal shops, where it is in regular use, to the exclusion of other artificial light; but I have preferred, in the following statement, giving the results from Messrs. Phillips and Lee's apparatus, both on account of its greater extent, and the greater uniformity of the lights, which rendered the comparison with candles less difficult.

"At the time I commenced my experiments, I was certainly unacquainted with the circumstance of the gas from coal having been observed by others to be capable of combustion; but I am since informed, that the current of gas escaping from Lord Dundonald's tar ovens had been frequently fired; and I find that Dr. Clayton, in a Paper in volume xli. of the *Transactions of the Royal Society*, so long ago as the year 1739, gave an account of some observations and experiments made by him, which clearly manifest his knowledge of the inflammable property of the gas, which he denominates 'the spirit of coals;' but the idea of applying it as an economical substitute for oils and tallow does not appear to have occurred to this gentleman, and I believe I may, without presuming too much, claim both the first idea of applying, and the first actual application, of this gas to economical purposes."

(811.) We see no just cause for objecting to this claim of Mr. Murdoch. At all events, the question seems to be within a narrow compass, that is, between Mr. Murdoch and M. Le Bon, a French engineer. Mr. Murdoch's first public exhibition was in 1802; but some years previously he had informed Mr. Watt of his experiments, and, according to the evidence of the latter before a Committee of the House of Commons, he had proposed to him to take out a patent for the invention in either 1795 or 1798. Now M. Le Bon, it appears, had actually exhibited his thermo lamp in 1801, and it was known in England that he had done so. The exhibition, therefore, of Mr. Murdoch at Soho would not of itself establish his priority, but there appears no question that he had already been engaged in the pursuit for some years; for seven at least, according to the evidence of

Claims of
M. Le Bon.

Manufac-
tures.

Mr. Watt, and, according to his own statement, for ten years; and, therefore, the only question seems to be, when did M. Le Bon commence operations? Mr. Winsor's claim to the invention appears to be quite out of the question, whatever merit may be due to him for the energy with which he pursued the subject, and urged it upon the attention of the Public.

In another part of his Paper the author describes the application of his invention at Messrs. Philips and Lee's establishment, above referred to, which it will be best to give in the Author's own words.

Gas works
of Messrs.
Philips and
Lee, Man-
chester.

(812.) "It is not my intention in the present Paper to enter into a particular description of the apparatus employed for producing the gas; but I may observe generally, that the coal is distilled in large iron retorts, which during the winter season are kept constantly at work, except during the intervals of charging, and that the gas, as it rises from them, is conveyed by iron pipes into large reservoirs or gasometers, where it is washed and purified, previous to its being conveyed through other pipes, called mains, to the mill. These mains branch off into a variety of ramifications, (forming a total length of several miles,) and diminish in size, as the quantity of gas required to be passed through them becomes less. The burners, where the gas is consumed, are connected with the above mains by short tubes, each of which is furnished with a cock to regulate the admission of the gas to each burner, and to shut it totally off when requisite. This latter operation may likewise be instantaneously performed, throughout the whole of the burners in each room, by turning a cock, with which each main is provided, near its entrance into the room.

"The burners are of two kinds: the one is upon the principle of the Argand lamp, and resembles it in appearance; the other is a small curved tube, with a conical end, having three circular apertures or perforations of about a thirtieth of an inch in diameter, one at the point of the cone, and two lateral ones, through which the gas issues, forming three divergent jets of flame, somewhat like a *fleur-de-lis*. The shape and general appearance of this tube have procured it among the workmen the name of the cockspur burner.

"The number of burners employed in all the buildings amounts to 271 Argands and 633 cockspurs; each of the former giving a light equal to that of four candles of the description above mentioned, and each of the latter a light equal to two and a quarter of the same candles, making therefore the total of the gas-light a little more than equal to that of 2500 candles. When thus regulated the whole of the above burners require an hourly supply of 1250 cubic feet of the gas produced from cannel coal; the superior quantity and quality of gas produced from that material having given it a decided preference in this situation over every other coal, notwithstanding its higher price.

"The time during which the gas-light is used may, upon an average of the whole year, be stated at least at two hours per day of twenty-four hours. In some mills, where there is over-work, it will be three hours, and in the few where night-work is still continued, nearly twelve hours. But taking two hours per day as the common average throughout the year, the consumption in Messrs. Philips and Lee's mill will be $1250 \times 2 = 2500$ cubic feet of gas per day, to produce which 7 hundred weight of cannel coal is required in the retort. The price of the best Wigan cannel (the sort used) is $13\frac{1}{2}d$ per hundred weight, ($22s. 6d$ per ton,) delivered

at the mill, or say about 8s. for the 7 hundred weight. Multiplying by the number of working days in the year, (313,) the annual consumption of cannel coal will be 110 tons, and its cost £125.

Mechanical
Processes.

"About one-third of the above quantity, or say 40 tons, of good common coal, value 10s. per ton, is required for fuel to heat the retorts; the annual amount of which is £20.

"The 110 tons of cannel coal, when distilled, produce about 70 tons of good coke, which is sold upon the spot at 1s. 4d. per hundred weight, and will therefore amount annually to the sum of £93.

"The quantity of tar produced from each ton of cannel coal is from 11 to 12 ale gallons, making a total annual produce of about 1250 ale gallons, which not having been yet sold I cannot determine its value; but whenever it comes to be manufactured in large quantities, it cannot be such as materially to influence the economical statement, unless indeed new applications of it should be discovered.

"The quantity of aqueous fluid which came over in the course of the observations which I am now giving an account of was not exactly ascertained, from some springs having got into the reservoir; and as it has not been yet applied to any useful purpose I may omit further notice of it in this statement.

"The interest of the capital expended in the necessary apparatus and buildings, together with what is considered as an ample allowance for wear and tear, is stated by Mr. Lee at about £550 per annum, in which some allowance is made for this apparatus being made upon a scale adequate to the supply of a still greater quantity of light than he has occasion to make use of.

"He is of opinion that the cost of attendance upon candles would be as much, if not more, than upon the gas apparatus, so that in forming the comparison nothing need be stated upon that score, on either side.

"The economical statement for one year then stands thus:

"Cost of 110 tons of cannel coal	£125
"Ditto of 40 tons of common ditto	20
	145
"Deduct the value of 70 tons of coke	93
"The annual expenditure in coal, after deducting the value of the coke, and without allowing any thing for the tar, is therefore	52
"And the interest of capital, of wear and tear of apparatus	550
"making the total expense of the gas apparatus about	£600 per annum.

"That of candles to give the same light would be about £2000. For each candle consuming at the rate of 4-tenths of an ounce of tallow per hour, the 2500 candles, burning upon an average of the year two hours per day, would, at 1s. per pound, the present price, amount to nearly the sum of money above mentioned.

"If the comparison were made upon an average of three hours per day, the advantage would be still more in favour of the gas-light; the interest of the capital and wear and tear of the apparatus continuing nearly the same as in the former case; thus,

" $1250 \times 3 = 3750$ cubic feet of gas per day, which would be produced by $10\frac{3}{4}$ hundred weight of cannel coals; this, multiplied by the number of working days,

Manufactures. gives 168 tons per annum, which, valued as before, amounts to £188
 " And 60 tons of common coal for burning under the retorts will amount to 30

218
 " Deduct 150 tons of coke at 26s. 8d. 140

" Leaving the expenditure in coal, after deduction of the coke, and without allowance for the tar, at 78

" Adding to which the interest and wear and tear of apparatus, as before, the total annual cost will not be more than £650, whilst that of tallow, rated as before, will be £3000.

" It will readily occur, that the greater number of hours the gas is burnt, the greater will be its comparative economy, although in extending it beyond three hours an increase of some parts of the apparatus would be necessary.

" If the economical comparison were made with oils, the advantages would be less than with tallow.

" The introduction of this species of light into the establishment of Messrs. Philips and Lee has been gradual, beginning, in the year 1805, with two rooms of the mill, the counting-houses, and Mr. Lee's dwelling-house. After which it was extended through the whole manufactory, as expeditiously as the apparatus could be prepared.

" At first some inconvenience was experienced from the smell of the unconsumed or imperfectly purified gas, which may in a great measure be attributed to the introduction of successive improvements in the construction of the apparatus as the work proceeded. But since its completion, and since the persons to whose care it is confided have become familiar with its management, this inconvenience has been obviated, not only in the mill, but also in Mr. Lee's house, which is most brilliantly illuminated with it, to the exclusion of every other species of artificial light.

" The peculiar softness and clearness of this light, with its almost unvarying intensity, have brought it into great favour with the work-people. And its being free from the inconvenience and danger resulting from the sparks and frequent snuffing of candles is a circumstance of material importance, as tending to diminish the hazard of fire, to which cotton-mills are known to be much exposed."

M. Le Bon's thermo-lamp.

(813.) Such was the state to which Mr. Murdoch had brought the application of coal gas in the course of the 16 years between 1792 and 1808, but from about 1802 to the same period, 1808, other ingenious individuals had pursued the same object, and it remains for us to state what had been the result of their experiments during the latter six years. It has been stated that a grand display of this light was made in 1802; Mr. Murdoch was at that time very desirous that Mr. Watt should take out a patent for the invention, but it was thought that the circumstance of Lord Dundonald having fired the gas at his Works, as already described, would interfere with any patent right. In the same year, 1802, Mr. Gregory Watt visited Paris, and there he found M. Le Bon, a French engineer, who had already, the year before, lighted up his house and gardens in Paris with gas obtained from wood and coal, and contemplated lighting up in the same manner some of the streets of that metropolis. The name which M. Le Bon gave to his furnace or apparatus was a Thermo-lamp.

This not only attracted the notice of the Parisians, but of foreigners, and amongst others Mr. Winsor; in consequence, the latter gentleman (as he informs us in his first pamphlet) made a journey from Frankfort to Paris, for the purpose of investigating the matter more minutely. He was not, however, allowed to see any part of the apparatus of M. Le Bon, except a small oven, and failed also in an attempt to make some arrangement with him for proceeding to England, and engaging in the manufacture of tar from English coal. Thus baffled, Mr. Winsor made experiments on his own account, and his first successful result was exhibited in the Autumn of 1802, at Brunswick, in the presence of the reigning Duke and other persons of distinction. This success induced Mr. Winsor to style himself, in the title page of his pamphlet, "Second inventor and improver," being, no doubt, at that time, ignorant of what had already been done at Birmingham by Mr. Murdoch.

(814.) In 1803 Mr. Winsor began his public exhibitions at the Lyceum theatre, in London, of coal-gas illumination, and in 1804 took out a patent for his invention.

The beauty of gas-light, as compared with that from common oil lamps, and the facility with which, by means of a proper arrangement of tubes and burners, it may be made to represent any fanciful or decorative figure, strongly attracted the attention of the Public to Mr. Winsor's exhibition. The earnest zeal and enthusiasm of the patentee likewise concurred powerfully to the same end; and, notwithstanding some very obvious and stupendous exaggerations in his estimate of the expected profits of the scheme, he soon acquired friends and supporters who enabled him, in the Spring of 1807, to light up a part of the south side of Pall Mall with coal gas, and thus demonstrate the practicability of his plan.

The jet and burners used in Mr. Winsor's exhibition, at the Lyceum, were nearly the same as those at present employed, but, as was natural to expect in a first and comparatively rude attempt, leaks were frequently occurring in the pipes, through which the gas escaped and annoyed his audience, and the gas even when burned produced unpleasant sulphureous exhalations, which were the subject of much complaint. To remedy this, the gas in its progress from the retort to the gasometer was passed through perforated plates at the bottom of a cistern of lime water, and afterwards milk of lime was substituted for the lime water with manifest advantage, the application of this liquor to the purification of gas being, it is believed, an original invention of Mr. Winsor.

In 1809, Mr. Winsor and his friends applied to Parliament for an Act of Incorporation, with liberty to raise a capital of £200,000; the application, however, was not successful, partly in consequence of Mr. Murdoch's opposition, who brought forward, apparently to the satisfaction of the Parliamentary Committee, his proofs of priority of discovery. The application, however, was renewed in the next year: though it encountered some opposition, and incurred considerable expense, yet the parties succeeded in obtaining an Act to authorize his Majesty to grant them a charter, within three years from the time of passing the Act. But the Bill, as originally introduced, was materially altered, and certain conditions were imposed, which limited their powers to London, Westminster, Southwark, and the suburbs adjacent. Besides, it was stipulated, that, if required, they should contract with the parishes of London, Westminster, and Southwark, to furnish a stronger and better light, and

Mechanical Processes.
 Mr. Winsor's propositions for a National Gas Company.

Applications to Parliament.

Manufactures.

at a cheaper and lower price, all expenses included, than such parishes could be supplied with oil, if lighted in the usual manner. Their capital was limited to £200,000, which was to be raised in shares of £50 each; they were not authorized to exercise any of the powers granted by the Act till such time as £100,000 were subscribed; and the Act also obliged them to raise the full sum of £200,000 within three years from the time the charter should be granted. For managing the affairs of the corporation, a governor, a deputy-governor, and ten directors were to be elected; and holders of two shares, and less than four, to have one vote; four and less than eight, two; eight and less than sixteen, three; sixteen and less than twenty-four, four; and twenty-four and upwards, five votes; and no person was to be entitled to vote unless he had held two shares, and had possessed them for six calendar months. A variety of minuter conditions were included respecting general Meetings, dividends, &c., which it is unnecessary to detail, but such is a general outline of the Act. Thus, by perseverance, the persons who had engaged in this great speculation succeeded in the attainment of the leading point which they had so anxiously sought; and Mr. Winsor's plan of a National Light and Heat Company was in part accomplished, by the legal formation of a local Gas-light and Coke Company.

Whatever reflections were made at the time the subject was so much agitated, it must be admitted that the zealous and unremitted exertions of the individuals engaged in this arduous business have been productive of very important consequences; but the advantages resulting from their success have proved beneficial to the Public in a much greater proportion than to the original projectors, or the present proprietors. From the extent to which gas-lighting has since been applied, if Mr. Winsor could have unquestionably shown his just right to a patent for the discovery, the pecuniary benefit he might have derived from it would have been very considerable; but, whatever praise may be due to him for attracting attention to the subject, it is now generally allowed that he was not the discoverer, and that his pretensions to be such had no foundation.

First Company incorporated.

The incorporation of this Company conduced to fixing the art of gas-lighting upon such a basis as promised its permanent establishment, and increased the probability of its ultimate success. Various and plausible as were the objections urged against it at the time, experience has proved that the property of an individual was neither adequate to the magnitude, nor likely to be risked, in such large and expensive undertakings; and this was shown by some facts adduced in the evidence to support the Bill. By calculations made from actual surveys, it appeared that the expense of laying down pipes for the city of Westminster alone would be £150,000, without including any thing else. There were also other circumstances that entitled this Company to particular attention; for, previously to this period, their experiments for making, purifying, and applying the use of coal gas to the purpose of lighting, had been made on a large and expensive scale; and although the Public had been partially benefited from the knowledge obtained by their means, hitherto no pecuniary advantage had resulted to themselves, notwithstanding their zealous exertions to improve and introduce the Art of gas-lighting. The hope of future benefits, however, animated them in their further efforts to attain their object. Perseverance enabled them to

overcome the great difficulties which attended their pursuits; the success of their endeavours has excited and encouraged others to engage in the same course and imitate their example; and how many similar Companies may trace their origin to the stimulus produced by the successful establishment of this!—Matthews's *Historical Sketch of Gas-lighting*.

(815.) Before we proceed to explain further the progress of this Art, it will be proper to introduce the name of another individual, who has perhaps contributed more largely to the practical improvement of it, and has invented more useful apparatus connected with it, than any other person whatever. In 1820 Mr. Clegg published a pamphlet with a view to claim his share in the invention of several Machines, some of which, he considered, had been unjustly pirated from him, and, without giving any opinion on this point, the following statement, as abridged from the pamphlet, by Mr. Matthews, in his valuable History, will show how largely the author contributed, in the infancy of the Art, in bringing it to its present state. His attention, he states, was first called to the subject in 1804, and in the following year he erected a gas apparatus at the cotton-mill of Henry Lodge, Esq., near Halifax, which was the first complete permanent Work of the kind in England. In 1806, the private house of the same gentleman was also lighted by him, and here he first attempted to purify the gas by lime introduced into the tank in which the gasometer floated. In 1807, he lighted the manufactory of Messrs. T. and S. Knight, of Longside, near Manchester, and, in 1809, that belonging to Mr. Harris, at Coventry, and here the paddle was employed for agitating the lime at the bottom of the tank. In 1811, he also erected a gas apparatus at Dolphinholme, near Lancaster; and, in the same year, another at Stoneyhurst College, Lancashire, where the first separate lime Machine was introduced. In the same year he lighted the mill belonging to Mr. Greenway, in Manchester, and here was the first introduction of the hydraulic main. These last two inventions have contributed very largely to the present extensive application of gas throughout the Country. In 1812, he erected two other gas Works, with some additional improvements; and, in 1813, he was chosen engineer to the Chartered Gas Company in London, and from that time the affairs of that corporation, which hitherto had to contend with great difficulties, began to revive; but, in 1813, an explosion having taken place at their Works in Westminster, the Government interfered, the question was referred to the Royal Society, who appointed a Committee to examine into the circumstances, and who made their Report in 1814, but which was not given to the Public till 1823, when a second Committee of the House of Commons was appointed to inquire into various subjects connected with gas establishments. Our limits will not allow us to give the particulars of this interesting inquiry to the extent we should have wished to have done, but the Report of the Committee, with some trifling abridgement, will itself be found very instructive and interesting.

(816.) *Report of the Select Committee of the House of Commons, appointed, in 1823, to make inquiries on various subjects connected with gas-lights, gas establishments, &c.*

"Your Committee are of opinion that the danger likely to arise from gasometers and gas Works is not so great as has been supposed, and that, therefore, the necessity of interference, by the legislative enactments

Mechanical Processes.

Mr. Clegg contributed largely to the success and perfection of gas Works.

Report of a Parliamentary Committee, 1823.

Manufac-
tures.

pointed out in the Reports referred to them, does not press at the present period of the Session.

"It appears that great improvements have taken place in the apparatus, Machinery, and management of gas Works since 1814, the date of the Report from the Committee of the Royal Society, which have very much lessened the danger of such Works; and that improvements are daily making in every department of them, which must still further lessen the danger necessarily attendant on such establishments.

"The evidence sufficiently supports the opinion that the risk of accident or danger is but small, if the ordinary care and attention necessary in every large establishment be paid by the officers and workmen employed on the premises.

"It is in evidence that the carburetted hydrogen gas usually supplied to the Public is not, of itself, explosive; but that, in order to render it so, a mixture of from five to twelve parts of atmospheric air, and the application of flame, is necessary; whilst the manner in which the gasometer houses are in general built renders it extremely difficult to form the mixture requisite for explosion, and consequently renders the chance of danger remote.

"The danger attendant on the use of gas in the streets and passages appears also to be small; and that it will, probably, by the better management and care of the persons employed in these establishments, be henceforth lessened.

"The Committee beg to refer to the evidence respecting the accidents, by explosions of gas, stated to have occurred at Edinburgh, Manchester, and other places, as to their extent.

"It appears that, in some of the gas Works, safety lamps, on Sir Humphrey Davy's plan, are used on the premises, to guard against accidents which might occur by the application of flame to any explosive mixture that may have been formed by leakage from the gasometers or pipes; and, as the Committee consider that precaution very necessary, they trust the Directors of every establishment will immediately adopt them, both for their own and the public security.

"There are several suggestions in the Reports, and in the evidence, as to the limits of districts, the size of gasometers, the distance of placing them from each other, the structure of the houses and roofs, the kind of tanks, &c., that deserve very serious attention; and, although the Committee view the interests of the gas establishments as intimately connected with the avoidance of danger from the gas, they are decidedly of opinion that such further power should be given to the Secretary of State, over all gas establishments, as shall be deemed requisite to carry into effect the improvements in the works that may be necessary for the safety of the Public.

"The Committee cannot close their Report without expressing their satisfaction that the Public have obtained so great and so rapidly increasing a means of adding to the convenience and comfort of society as the use of gas, under due management, must afford; and they are of opinion that, as a means of police, much benefit would be derived from its general introduction to light the streets of this metropolis.

"Your Committee have deemed it proper to add to their Report, by way of appendix, the examinations of the several witnesses called before them; and they beg leave to refer generally to the printed Reports of the Royal Society and of Sir William Congreve.

(817.) "Sir Humphrey Davy, Bart., President of the Royal Society, examined. Mechanical Processes.

"Have you seen the Report that was made by a Committee of the Royal Society, in the year 1814, respecting the explosion which had then lately taken place in the gas works at Peter Street, and with respect to the dangers that are liable to occur in gas Works?—I have read that Report with great attention. Evidence of Sir H. Davy.

"Do you think the estimate of the possible explosive force of a gasometer of 14,000 cubic feet is overrated, when, as stated in that Report, it is compared with an explosion of 10 barrels of gunpowder in its most favourable circumstances, and supposing the least explosive force that it is capable of?—I should conceive, certainly, it is not overrated.

"Do you conceive that the danger of explosion from the gasometer increases with the size of the gasometer?—Beyond all question; there is not more danger of explosion, but more danger from the explosion.

"The size does not make the danger, but it augments the fire when the explosion takes place?—Just so.

"Are you to be understood that you think a large gasometer as manageable as a small one?—I should suppose not; but what ingenuity can do, and what Machinery can do, is a question it is impossible for any individual to answer.

"Is it not probable that lightning might produce an explosion in a charged gasometer, by rending the gasometer at the moment that the lightning struck it?—Supposing lightning to pass through a conductor of electricity, which is highly improbable, at least in such a way as to make an aperture, it might produce combustion; I think it would not produce explosion: supposing an aperture made by lightning, by which the gas might escape, it would come out as an immense column of flame, but I think without explosion.

"If the whole contents of a large gasometer were sufficiently inflamed by lightning, or any other cause, do you not apprehend that serious mischief would be done to the neighbouring gasometers, and to the building surrounding the gasometer so struck?—I should think the roof of the building would be destroyed.

"Might not a sudden conflagration produce an extreme rarefaction and concussion that would produce the same effect, in some measure, as an explosion?—It is necessary to premise, with respect to that question, that the gas in a gasometer can only explode when mixed with at least five times its volume of air, and it will explode when mixed with ten times its volume of air; now, supposing, what appears to be an almost impossible case, of an aperture made by lightning in the upper part of the gasometer, a large aperture of two or three cubical feet, the lightning, in making that hole, would of course inflame the gas, and the pressure of the atmosphere would cause the elastic fluid to flow out as an immense column of flame; but I do not conceive the effect would be the same as that of an explosion; it would be quite a different effect. I should rather think it would not destroy the gas-holders, unless any part of the flame came in contact with the iron of the gas-holders; suppose the hole struck in the side of the gasometer, the column of flame would flow laterally, and might injure the other gasometers.

"Have you seen the gas Works in Peter Street?—I have to-day.

"There are from fourteen to fifteen gasometers, not in

Manufactures.

actual contact, but placed very near together; what do you conceive the effect of the explosion of one of the largest gasometers in Peter Street would be amongst the other gasometers in those Works?—It is extremely probable that they would be overturned, torn in pieces, removed from their situations, and the whole exploded; but it is very difficult to answer that question, because it is a matter of experimental research; and, if I wanted to ascertain whether they were likely to be exploded, I should have a model of them made on a small scale, and introduce an explosive mixture into one, and ascertain what the effect would be upon the others. I think an experiment of that kind would be more satisfactory than any opinion I can give; when we act on a great scale, the results are not always the same; when we argue from the force of gunpowder, they are not exactly the same; they are both extremely dangerous, but nobody can predict the exact result.

“Supposing one gasometer exploded, and that there were three or four in the neighbourhood, as in Peter Street, would the chance of the explosion communicating to the adjoining gasometers be as great as it would be if one barrel of gunpowder exploded among three or four other barrels of gunpowder?—Not nearly so much; the flame is less intense, the heat is less, and there is a possibility that, in the open atmosphere, a gasometer at the distance of 50 or 60 feet might not be destroyed; it would depend entirely on the force of the explosion. If a person were to make the most explosive mixture, the effect would be very different from an explosion; from a small quantity of air there would be a range of differences in intensity, from one to twenty times; if the smallest quantity of air which produces explosion happened to be in the gasometer, the explosion would be a small one; if the largest proportion, the force of the explosion would be very great.

“Do you think that, as the gas establishments are at present conducted, the chances of explosion are great?—No; very small.

“Do you think it most probable, since the year 1814, that such improvements have been introduced into the mode of fixing the gas-holders, and other improvements, that, at present, the chances of explosion are comparatively slight to what they were when this Report was made?—As I did not examine at the time, I cannot say; I have never seen any gas establishment till this morning; it appears to me, from the short examination I made, that the chances of explosion are exceedingly small; they must be so, indeed, from the length of time which has elapsed since any explosion of consequence has taken place.

“There are three chances of explosion, according to this Report; namely, in the gas-holder, after the gas is expelled from the gas-holder and introduced into the pipes, and, afterwards, in the houses where the gas is lighted?—Yes.

“Do you think it necessary, in the regulations, to guard against the explosions that may take place in the mains under the streets, or where the lamps are lighted in the different shops?—I believe the Report of the Royal Society states, that there is no chance of explosion in the pipes; that the explosion does not pass down through a pipe of that diameter.

“The question refers to leakage?—Yes, a mixture being made; I believe there have been some explosions in shops, but then they would not act to any extent, they would be only limited to a very small space.

VOL. VII.

There is one great source of advantage in the coal gas, which is the large quantity of common air it requires to be mixed with it to produce explosion. Mechanical Processes.

“A very powerful explosion may be produced by three parts of atmospheric air?—I have been able to produce in the coal gas I have made, by four parts, a very slight explosion, but eight or nine parts produced the maximum of explosion in the experiments I made.

“You have said you were generally satisfied with the Report made by the Royal Society, with the exception of the extent to which they have limited the gasometer?—My feeling was, that they had not exactly considered that part of the subject; and, perhaps, at that time it was not supposed gas establishments would be so extensive. I think it would be inconvenient to the Gas Companies to make gasometers on so small a surface; it would be more expensive. I think a gasometer, containing 12,000 cubical feet, would not be dangerous, if properly separated from other gasometers.

“In fact, you think, with proper caution, a gasometer containing 20,000 cubic feet is removed pretty well from danger?—I think so; the danger must be increased according to the size both of the object bursting and the explosion from it.

“It is not more difficult to make an explosive mixture in a large gasometer than a small one?—More difficult, certainly, by the same aperture; it would take more time; the time would be greater in proportion as the contents of the gasometers were more.

“It would take a greater length of time to create an explosive mixture in a large than a small one?—By the same aperture, certainly.

“You think there would be no explosion from lightning, but that the gas would be inflamed, and ascend in a column of flame?—I think it is almost impossible that inflammation from lightning can take place, for a gas-holder is so good a conductor, that every discharge from a cloud in the electrical state would pass down the sides of the gasometer. I see no reason why it should pass into the gasometer; it is, in my opinion, almost an impossible case.

“You just stated a reason for considering coal gas to be particularly safe; did you mean that it was more safe than any other?—There are gases which require still larger portions; oil gas, for instance.

“Do you consider oil gas preferable to coal gas?—In every respect as far as lightning is concerned.

“As far as danger is concerned?—There is less, certainly.

“Does it require a greater quantity of atmospheric air to produce an explosive mixture?—It does.

“In what proportion more, taking five parts as to coal, what should you state as to oil?—I have never made any experiments upon the subject; pure olefiant gas requires a larger proportion; it does not explode powerfully with less than eight parts; it requires six to produce a mixture which will be at all explosive.

“Then the Committee are to understand, that the danger arising from explosion in one of the large gasometers would not be proportioned to the number of cubic feet they actually contained, but to the proportion in which that is mixed with atmospheric air?—Certainly.

“Then a gas-holder, containing 20,000 cubic feet of gas, might explode without any very great danger to the neighbourhood?—It could not explode at all without danger. To make the greatest explosive effect would

Manufac-
tures.

require 18,000, or 16,000, or 17,000 cubic feet; therefore, it ought to contain above 2000 feet of gas at the time.

"In proportion to the size of the gasometer is the difficulty of inflaming that gas?—Not of inflaming, but of making an explosive mixture from the same aperture.

"Not the danger in point of facility, but in point of time; it would require a longer time?—Yes; and the effect would be much more dangerous when it took place; but there would be a greater chance of discovering a leak in consequence of the longer time required.

"If a leak were to be made in a gas-holder, and the gas, by escaping, were to mix itself with the surrounding air, would not that produce such a smell that even the least skilful of the persons in the habit of managing the gas establishments would be put upon their guard, so as to take precautions against the danger that would arise from fire being supplied?—Yes; unless the delicacy of smell, the sensibility of the olfactory nerves, were blunted by habit; which, however, I suppose is not the case.

"Would you feel yourself competent to advise this Committee as to the danger or safety of Works of such extent, without having an opportunity of visiting them in person?—Certainly not.

"You have stated, that you should feel it necessary to make certain experiments before you could pronounce positively; those experiments have not been made?—I have had no motive for making them, nor should I make them personally; but, if I required such results, I should get them made.

"Have you ever known of any accident, either by way of bursting or explosion, happening to a gasometer, or a gasometer-room?—I think I have seen in the newspapers some such accounts, but I do not recollect them with precision.

"Assuming that, since the year 1814, the gasometers had increased in number from one to forty-seven, and their contents from 14,000 cubic feet to 917,000 cubic feet, and that no explosion or bursting either of a gasometer or a gasometer-room should have taken place during that period, would not that, in your mind, afford an inference both as to the safety of their construction and the care of their management?—I suppose so. It is a question of probability; it does not appear to me to be at all of the nature of a scientific question. I have already stated that I think the probability of explosion very small.

"William Hyde Wollaston, M. D., examined.

Evidence
of Dr. Wol-
laston.

(818.) "If a gasometer were overturned by a burning roof, would not the sudden conflagration of the gas, so discharged, produce something equivalent to an explosion?—It is difficult to judge; I never saw so large a quantity fired. The name which that gas originally had, was lambent inflammable, from its tardy combustion. If you have two vessels set side by side, one of common hydrogen, the other of carburetted hydrogen or coal gas, and turn up one and set fire to it, you have an immediate explosion, from the instantaneous mixture of pure hydrogen with the common air; but if you turn up the other, and set fire to it, you have a lambent flame. It was called Lambent Inflammability, in consequence of the slowness of the combustion which takes place.

"Do you apprehend that any serious mischief might be done by lightning striking the gasometer?—I cannot conceive it at all; I cannot conceive lightning setting fire to the gas which is contained in it

"Not if it were to pierce the gasometer?—Supposing it threw down the building, all the effect of lightning must be gone before that gas can mix with common air.

"If it were to rend the gasometer, would there not be a probability of inflammation at all events?—I do not understand how the lightning itself can rend the gasometer; the gasometer being of metal, I do not see how it can be rent by it.

"If any one of those gasometers, by design or by accident, were to explode, what do you conceive would be the probable result with respect to other gasometers at no great distance from the exploded one?—It is not probable, I think, that an explosion would take place; it is much more likely that they would burn slowly, from being burst. If a sudden bursting of a gasometer took place in the presence of fire, I would not expect an explosion in consequence; I may be wrong.

"Suppose an explosive mixture to exist in one gasometer, either by accident or design, and fire put to it, what do you apprehend would be the effect on the neighbouring gasometers?—It would much depend on the relative distance of the party-wall. A strong party-wall might be thrown against an adjacent gasometer, and burst it; it is probable it would not take fire; the gas would escape; but, even if there were fire present, I should not expect any sudden explosion to take place in the neighbouring gasometer.

"You were one of the Committee of the Royal Society that signed this Report in 1814?—I was.

"In this Report I find this passage: 'The receiver is suspended and balanced in such a manner, that the water in the tank shall be kept about half an inch above the level of the water in the receiver, and this constitutes the pressure by which the gas is forced out to feed the lamps; as long as every part of this reservoir is kept in good repair, and perfectly tight, the pipes leading into and out of it maintained in proper condition, and plenty of water supplied, so that the parts which ought to be under water shall never be left bare, it seems to your Committee scarcely possible that any explosion should take place; but, under the management of an unskilful or negligent superintendent, defects might occur in different parts of the Machinery, by which the gas might come to be mixed with common air, and give rise to the most dangerous explosions.' Since the year 1819 have you had any occasion to alter this opinion?—I know that such accidents can occur, but they occur but rarely; I know but of three or four instances. These are, one which took place at Newcastle, one that took place at the Custom House, and the third at Savory and Moore's in Bond Street; there was another, I believe, under the Arcade, at the Opera House.

"Have you known of any within the last twelve months?—I do not happen to know of any one within the last twelvemonth.

"Do you know that great improvements have been made in the gas apparatuses since the period when this Report was made?—I am persuaded there must have been improvements; but I cannot say that I know of them.

"You say, that the proportion to make the greatest explosive mixture is in the ratio of nine to one?—Nine or ten to one.

"Then, in a gasometer holding 20,000 cubic feet, there could be more than 2000 cubic feet of the gas when the explosive mixture was at the highest?—Certainly.

Mechanical
Processes.

Manufac-
tures.

"Upon that occasion, granting that an explosion would take place in its greatest possible degree, the whole explosion of a gasometer holding 20,000 cubic feet would not be quite the proportion of two barrels of gunpowder?—This involves the question put before; and, upon that, I should be glad to know how many pounds there are in a barrel of gunpowder. (It was stated to the witness that it was 100 pounds net.) Then I will draw an inference from Sir William Congreve's experiment, (subject to his correction,) that if 1 cubic foot is equal to half an ounce, 3200 cubic feet of the same mixture will be required to be equal to a barrel of gunpowder; which 3200 feet appears a near coincidence with the Report of the Royal Society, stating 3000. But the proportion of the mixture, in his experiments, it appears, is different.

"Then those 3000 are 3000 cubic feet of the gas unmixed?—No; 3000 feet of the mixed gas. The experiment that seems to concur with the note in the Report, gives 3200 feet of the mixed gas, of which one-tenth would be 320 feet of coal gas, equal to a barrel of gunpowder; but it is mixed here in the proportion of one to five, instead of one-tenth.

"You are taking this from the experiment before you, and not giving it as the result of your own experiment?—Certainly; I am giving it here just as I find it.

"Do you think there is more danger and more difficulty in the management of a gas-light establishment than there is in the management of gunpowder?—Most certainly not; most certainly much less precaution is necessary against accident.

"Do not you believe that the best safety to the Public, superior to all regulations and all rules laid down by Act of Parliament or otherwise, will be in the safety of the management of their own property by those different Companies?—It appears to me that the Government may rely upon the interest of the parties to take all the precaution they can.

"In your opinion, supposing the establishments to be conducted by very skilful and attentive persons, is the danger of explosion, under such circumstances, small or great?—I presume it to be very small. It requires such a concurrence of circumstances to have an explosion take place; the admixture of a due proportion of common air with the gas, and then fire to be put to it at the proper time; there are various cases in which two circumstances are requisite, and various others in which three are requisite. I do not recollect having noted more than three; but where three conditions are requisite, the probability is so remote that I should not trouble myself to estimate the danger.

"You state that the proportion to give the strongest explosion is from nine to one?—Nine or ten to one.

"Are the Committee to understand that it has been ascertained that after that the explosion weakens?—Yes, that is what I mean to say. I understand that if the air is increased to eleven or twelve to one, the explosion is weaker and weaker. Where the explosion terminates I do not know; but this I would say, that, when the quantity of common air exceeds the due proportion, explosion is sudden, though less violent; but when the air is deficient in quantity the explosion will be slower.

"If it is explosive, will it not always be sudden?—No; there are degrees of rapidity of explosion between the proportions of ten to one and that of five to one; for instance, when the quantity of air is redundant, if the mixture fires at all, the whole goes off; but, when the

air is deficient, part of the gas fires by progressive admixture with fresh air.

Mechanical
Processes.

(819.) "John Millington, Esq., examined: a civil engineer and professor of Mechanical philosophy in the Royal Institution.

"Have you seen a Report of the Committee of the Royal Society which was laid on the table of the House of Commons?—I have. Evidence of Professor Millington.

"Do you think the calculation of the explosive force of gas, as compared with gunpowder, in that Report is overrated?—I believe it to be quite correct.

"Have you seen Dr. Young's calculation of the comparative force of gas and gunpowder?—I have not.

"Sir William Congreve stating that this was the calculation referred to in page 1 of the Report of the Committee of the Royal Society, by the words, 'A calculation of the probable force of an explosion of the gas,' was communicated by one of the Members; the same was delivered in and read as follows:

(820.) "*Estimate of the Force of Explosion of Coal Gas, laid before the Committee of the Royal Society in the year 1814, by one of its Members.*

"It must be confessed that, without direct experiments in the force of any exploding compound, we can obtain nothing more than probability by calculating from the analogy of other similar effects; but, provided that we take sufficient care not to underrate the forces in question, we may obtain from such a comparison at least a useful estimate of their greatest possible magnitude. Consequences of explosion

"Dr. Henry has found (*Phil. Trans.* 1808) that coal gas requires for its combustion about twice its bulk of oxygen gas, and affords a little more than its bulk of carbonic acid; now, since common air contains only 21 per cent. of oxygen, it can combine with no more than 12 per cent. of coal-gas; so that 112 parts of the mixture contain but 33 of substances capable of affording heat, while the remainder tends in some measure to impede their union; hence, we cannot suppose the heat thus generated to exceed about one-fourth of the heat which would be excited in the mixture of the gas with pure oxygen; and we shall probably exceed the truth in allowing to the combustion of such a mixture a heat equal to that which is evolved in the deflagration of gunpowder, which is sufficient upon the most probable estimate to increase, in the ratio of 1 to 80, the natural elasticity of the fluids generated, which amount to 250 times the bulk of the powder, so that the elasticity thus augmented becomes equal to 20,000 atmospheres. It is true that some of the solid substances contained in gunpowder may possibly be converted into vapour, and may contribute to its effect; but we have no sufficient reason to believe that the vapours of any of these substances would be more elastic than air; and Count Rumford's hypothesis, concerning the effect of steam, is every way inadmissible, since, even if nitre contained water of crystallization, its vapour would be little more effectual than an equal weight of the gaseous substances.

"We may, therefore, suppose the exploding mixture to acquire a degree of heat capable of increasing its elasticity in the ratio of 1 to 20. Dr. Ingenhouz, following Robins, makes the explosive force of a mixture of oxygen and hydrogen equal to 4 atmospheres only; but the assumption of a degree of heat equal only to that

Manufac-
tures.

which Robins obtained in a fire, is wholly arbitrary, and a single drop of ether in a bottle of oxygen appears to have exploded with a force much more than commensurate to such a cause. On the other hand, when we consider with what safety a mixture of oxygen and hydrogen may be made to explode in a common quart bottle of green glass, we cannot hesitate to allow that 80 atmospheres must be a very ample estimate of the force of explosion of a mixture of oxygen and coal-gas. As the ignited gas expands, it loses a portion of its elasticity, not only by the diminution of its density, but also by the effect of the expansion on its temperature, which may be estimated as altering the elasticity in the proportion of the biquadrate root of that of the densities. Calculating upon these grounds, we find that the whole mechanical power of an explosion of 15,000 cubic feet of a mixture of coal-gas and common air is equal to that of the explosion of 6 cubic feet, or 4 barrels of gunpowder; and if we suppose the heated gases in both cases to escape and mix with the common air in a building containing 30,000 cubic feet, so as to produce an effect commensurate to the temperature of the whole mixture, the explosion of about 15 cubic feet or 10 barrels of gunpowder would be required, in order to produce, like the gas, a force of about 10 atmospheres for the whole space. It must, however, be recollected, that gunpowder thus disposed is very unfavourably situated for producing violent effects; and that a much smaller quantity, in ordinary cases, would be more formidable than the explosion of the coal-gas. A more precise idea of the effects of such an explosion may be obtained from the calculation of its projectile effects, which would carry some parts of the wall of the surrounding building to a height of nearly 150 yards, and others to a distance of nearly 300. If the walls were in immediate contact with the gasometer, the height and distance would be twice as great; but a roof of carpentry and tiles, being lighter, would be carried higher, while the lateral force of the explosion would be diminished.

"Supposing the explosion of the gas to be unconfined, the shock would throw down a brick wall of 9 feet high and 18 inches thick, at a distance of about 50 feet from the centre; it would probably break glass windows at 150 yards, and at 300 would produce an effect similar to the instantaneous impulse of a very high wind.

"Calculation.

Calcula-
tion of the
force by Dr.
Young.

(821.) "In order to compare the whole force of expansion in a confined channel, let the length occupied initially by the gas be a ; then, when it becomes ax , the elasticity will be diminished in the ratio of 1 to $x^{\frac{5}{4}}$, and the force will be expressed by $nx^{\frac{5}{4}} - 1$, and the fluxion of half the square of the velocity by $nax^{\frac{5}{4}} - ax$; and the fluent will be $-4nax - \frac{1}{4} - ax$, which is initially $-4na - a$; and, finally, when $nx^{\frac{5}{4}} - 1 = 0$, or $x = n^{\frac{4}{5}}$ and $n = x^{\frac{5}{4}}$, $= -4ax - ax$, and the difference, showing half the square of the velocity generated, is $(4n + 1 - 5n^{\frac{4}{5}})a$. When $n = 20$, the expression becomes $26a$. When $n = 20,000$ it becomes $66,204a$; and in order to make these values equal, the latter value of a must be $\frac{1}{2540}$ of the former, whence $\frac{15,000}{2540} = 5.9$.

"In a similar manner, when a is the radius of a sphere, or of a hemisphere, which expands in every direction, the elasticity will vary as $x^{-\frac{15}{4}}$ and the fluxion will be $nax^{-\frac{15}{4}} - ax$, and the fluent $-\frac{4}{11}nax^{-\frac{11}{4}} - ax$,

which, being corrected, gives for the half square $(\frac{4}{41}n + 1 - \frac{15}{11}n^{-\frac{4}{11}})a$. The fluent thus found may be compared with the feet in which the force of gravity would produce an equal velocity, by increasing it in the ratio of the pressure of an atmosphere to the weight to be moved, that is, for a brick wall 18 inches thick, multiplying it by 11; so that when $n = 20$ and $a = 15$, $5242a = 865$ feet, the height of ascent; or, supposing the space doubled, and $n = 10$, and a about $18\frac{1}{2}$, the height would be 430 feet.

Where the explosion of the gas takes place without an obstacle, the mean force being about $\frac{5242}{2.223}$ atmo-

spheres, the velocity of expansion will be about 2000 feet in a second, or perhaps a little greater, on account of the lightness of the gas; but this excess will be compensated when the velocity is afterwards communicated to the surrounding atmosphere; with this velocity, the centre of inertia of each elementary pyramid of the sphere will advance from the distance $\frac{3}{4}$ of 15 to $\frac{3}{4}$ of 33.35 feet through $13\frac{3}{4}$ feet in $\frac{1}{145}$ of a second; and, at any greater distance d , the velocity of the impulse will be

reduced from 2000 to $2000 \frac{25}{d}$ or $\frac{50,000}{d}$, its duration

being always $\frac{1}{145}$ of a second. Thus the velocity of a very high wind, being 60 feet in a second, the impulse would retain this force at the distance of 833 feet; and in order to determine at what distance it would overset a wall 9 feet high and $1\frac{1}{2}$ thick, we must first find the height through which the centre of oscillation of the wall at $\frac{2}{3}$ of its height must ascend; and in order to be immediately over the point of support, that is,

$\sqrt{(36 + 1)} - 6 = \frac{1}{12}$ of a foot, and the velocity corresponding to this height would be generated by the force of gravity in $\sqrt{\frac{1}{193}} = \frac{1}{13.9}$ of a second: and in order

to be generated in $\frac{1}{145}$ it requires a force 10.43 times as great, or equal to the pressure of a column of brick 15.64 feet high, that is, $15.64 \times 125 = 1955$ pounds for every square foot, which is equivalent to the pressure occasioned by a velocity of 966 feet in a second, and answers to a distance of 52 feet.

"Does it not appear from the Paper, that the calculation in the *Report of the Royal Society* intends to state that it is a mixture contained in the gasometer of 15,000 cubic feet which is equal to four or five barrels of powder, not of 15,000 cubic feet of gas, but a mixture that would be contained in a gasometer of that size? —In reading the *Report of the Royal Society*, it certainly appeared very clear to me that it was mixed gas which was alluded to in the Report. In this Paper, which professes to come from Dr. Young, mixed gas is stated, and therefore there can be no doubt about it; but, at the same time, there is such a want of accordance between the two accounts given in the *Report of the*

Mechanical
Processes.

Manufac-
tures.

Royal Society and in this Paper, that I can hardly conceive how they can be supposed to refer to each other; for in the Report, near the bottom of page 4, it is said, 'As to the effect of an explosion, if it should take place, the best calculation that has been made from data not very exactly determined is, that in a reservoir containing 14,000 cubic feet, it would not, under circumstances the most favourable to the explosive force, be equal to the effect of 10 barrels of gunpowder; and on an average of all circumstances would seldom exceed that of five.' Now Dr. Young, in this Paper, says, 'Calculating upon these grounds, namely, the previous ones explained in the Paper, we find that the whole mechanical power of an explosion of 15,000 cubical feet (instead of 14,000) of the mixture of coal gas and common air is equal to an explosion of 6 cubic feet, or 4 barrels, of gunpowder,' instead of 10 or 5 as the minimum. On referring to this Paper it appears that Dr. Young's name is not to it. I beg to say, that what I stated was not in the way of objection to this calculation; it was merely as to the want of accordance in the two Papers. If I am asked, whether those gases are explosive, and can produce as injurious effects as gunpowder, I should say, Yes; and I have already said, that I do not think that the force of gas is overrated in this Paper; I think that, when it takes fire, the force of it is as great, and will do mischief as great, as gunpowder.

"You state that opinion from experiments made by yourself?—Yes.

"And not founded on the experiments of any other individual?—Upon my own, certainly; corroborated by those of others.

"You have no doubt that the interpretation of that paragraph in the Report is, that it is only a portion of the gas that would be contained in a 14,000 feet gasometer, as there designated, and not the explosion of the whole 15,000 feet?—Yes.

"Dr. Young there states, that the effect produced by the explosion of a gasometer of 15,000 cubic feet, on the surrounding building, would be equal to 10 barrels of gunpowder?—That is the case.*

"You are to be understood, that the explosion of a gasometer of 15,000 cubic feet would produce on a surrounding building, the cubical contents of which were 30,000 cubical feet, an explosion equivalent to 10 barrels of gunpowder?—It is impossible for me to say that certainly; from Dr. Young's correct mode of working, I can generally state that I believe what he has done to be perfectly correct; but, from the cursory manner in which I have looked at this calculation, I cannot speak to it; but that is my understanding of the Paper, 'Calculating upon these grounds, we find that the whole mechanical power of an explosion of 15,000 cubical feet,' instead of 14,000, 'of mixture of coal gas and common air, is equal to that of 6 cubic feet or 4 barrels of gunpowder;' and if we suppose the heated gases in both cases to escape and mix with the common air, in a building of 30,000 cubic feet, so as to produce an effect commensurate to the temperature of the whole mixture, the explosion of about 15 cubic feet, or 10 barrels of gunpowder, would be required in order to produce, like the gas, a force of about 10 atmospheres for the whole space.

"Have you yourself tried any experiments to ascertain the comparative explosive force of gas and gunpowder?—I have not.

* "By this answer I meant that it was correct that Dr. Young had so stated the effect.

"Are you of opinion that the explosive force of gas may not increase in more than a direct ratio with respect to the increase of the quantity exploded?—I certainly think it would not do so; I see no reason for supposing it should.

"Have the goodness to look at the paragraph in the *Report of the Royal Society Committee* which relates to the explosion of Mr. Lukin's seasoning-house in Woolwich dockyard, in page 4. (The witness read the paragraph.)

"Are you aware of the size of the cubical contents of the seasoning-house which is there mentioned?—Not at all.

"If you were told that the cubical contents of that building did not exceed 8000 cubic feet, would you not imagine that the effect produced by that explosion was greater than would be due to an explosion of gunpowder, in the ratio stated in the *Report of the Committee of the Royal Society*?—The fact is, all experiments on the force of explosions depend in a great measure, or entirely, on the obstruction given to the explosion. Now I do not know what the seasoning-house was; if it was a close building, and a sufficient quantity of gunpowder or gas was exploded in it, I have no doubt it would knock it all to pieces; while if that same combustible was exploded in a room where there were no glass windows, and which was open to the air; or if a barrel of gunpowder were fired in Lincoln's Inn Fields, or any large square, without confinement, it would produce no injurious effect on any of the surrounding houses; whereas, if bound round by canvass, or enclosed in an iron shell, it might produce most dreadful consequences; therefore the effect of the explosion must be comparative, and will depend upon the confinement of the combustible; and unless I were acquainted with the particular construction of the seasoning-house I cannot give an opinion.

"Taking it for granted that the dimensions were such as to give a content of 8000 cubic feet, what quantity of gunpowder would those 8000 cubic feet be equal to, according to the rule laid down in the preceding paragraph?—Between 4 and 5 barrels of gunpowder, taking the average of the two statements. I take the ten and the five as giving the average; but, at the least statement, it would perhaps then not be quite equal to two and a half.

"Do you believe that two barrels and a half of gunpowder would produce such an effect as is stated in the account of the seasoning-house at Woolwich?—If the seasoning-house was a perfectly close building, and there were no possibility for the expanded air to escape, I apprehend it might.

"It has been stated, that one of the great difficulties of exploding a gasometer was from the great quantity of atmospheric air required to mix with the carburetted hydrogen?—That is the case.

"Would not that great quantity that tends to the security of the gasometer become a source of great danger to the surrounding building; would not that which gives security in the one case produce danger in the other?—Does that mean to infer that good ventilation, or a greater quantity of atmospheric air being admitted into the gasometer-house, would increase the danger? If so, I should say not.

"Whether a small quantity of gas escaping from the gasometer would not produce a dangerous mixture in the surrounding building; and, consequently, that pro-

Mechanical
Processes.

Manufac-
tures.

perty which makes it difficult to explode a gasometer would make it easy to explode a gasometer-house?—If that gasometer-house were close that certainly would be the case.

“In very calm weather do you apprehend that a leaky gasometer might not produce an explosive mixture in the surrounding building?—That must depend entirely upon the construction of the building; for as the gas is much lighter than the surrounding air, and if we presume the leakage to take place without any very great degree of rapidity, the gas from its specific levity would ascend through the tiles or openings of the roof as quickly as it would escape from the gasometer, unless such a roof was applied as would prevent the possibility of such escape; if, for example, a slated roof, or a ceiled roof, or a vault, were placed over a gasometer, there is no doubt that an explosive mixture would accumulate there.

“Is there not so strong a chemical attraction between gas and atmospheric air that the lighter air will even descend to mix with the heavier?—That must be a slow process.”

Description of the present process of Gas making.

Abstract
from the
evidence of
Sir Wil-
liam Con-
greve.

(822.) We cannot pursue the above interesting Report to a greater length, but a few facts drawn from Sir William Congreve, one of the Members of the Committee, and official superintendent of the London Gas Works, showing the extent to which they had then (*viz.* in 1823) arrived, is too interesting to be passed over, and with this we shall conclude this historical sketch, and beg to refer those who are desirous of a more circumstantial account of the progress of the Art to Matthews's *History of Gas Lighting*, which will be found to contain a clear and candid statement of all the prominent facts of the history.

In the Report alluded to, Sir William Congreve states as follows:

Statement
of the state
of the Gas
Companies,
&c. 1823.

“At the Peter-street station, the whole number of retorts which were fixed was 300; the greatest number working at any time during the last year 221; the least 87. Fifteen gasometers, varying in dimensions, the contents computed on an average at 20,626 cubic feet each, amounting to 309,385 cubic feet altogether, but never quite filled; the working contents estimated at 18,626 cubic feet each, in the whole at 279,390 cubic feet. The extent of mains belonging to this station is about 57 miles, there being two separate mains in some of the streets; the produce of gas from 10,000 to 12,000 cubic feet from a chaldron of coals. The weekly consumption of coal is reckoned at 42 bushels for each retort, amounting to about 602 chaldrons; and, taking the average number of retorts worked at this station at about 153, would give an annual consumption of coals of upwards of 9282 chaldrons, producing 111,384,000 cubic feet of gas. The average number of lights during the year 1822 was 10,660 private, 2,248 street lamps; theatres, 3,894.

“At the Brick-lane Works, the number of retorts which were fixed was 371, the greatest number worked 217, and the least 60. The number of gasometers 12, each averaging 18,427 cubic feet, amounting in the whole to 221,131 cubic feet; and their average working contents 197,124 cubic feet. The average number of retorts worked was 133, the coals consumed 8060 chaldrons; the quantity of gas produced was 96,720,000 cubic feet, the number of lamps 1,978 public, 7,366 private, through 40 miles of mains.

“At the Curtain-road establishment, the whole number of retorts was 240; the greatest number worked in the last year, 80; the lowest, 21. The number of gasometers, 6; average contents of each, 15,077 cubic feet; the contents of the whole, 90,467; another gasometer, containing 16,655 cubic feet; the average number of retorts worked, 55; the coals consumed, 3336 chaldrons; quantity of gas produced, 40,049,000 cubic feet; the number of lamps supplied, 3860 private, and 629 public, through 25 miles of mains.

“The whole annual consumption of coals by the three different stations was 20,678 chaldrons; the quantity of gas produced, 248,000,000 cubic feet; the whole number of lamps lighted by this Company, 30,735, through 122 miles of mains.

“The City of London Gas-light Company, Dorset-street.—The number of retorts fixed, 230; the number of gasometers, 6; the largest, 39,270 cubic feet, the smallest, 5428 cubic feet; two large additional gasometers nearly completed, contents of each, 27,030 cubic feet, making in the whole 181,282 cubic feet. The number of lamps lighted, 5423 private, and 2413 public, through 50 miles of mains. The greatest number of retorts worked at a time, (in 1811,) 210, the least, 130, average 170. The quantity of coals carbonized amounted to 8840 chaldrons; produced 106,080,000 cubic feet of gas.

“The South London Gas-light and Coke Company, at Bankside.—The number of retorts was 140; gasometers, 3; the contents of the whole, 41,110 cubic feet; and their mains from 30 to 40 miles in length. At their other station in Wellington-street, they had no retorts in action; but three large gasometers were erected, containing together 73,565 cubic feet, which were supplied from Bankside till the retorts were ready to work.

“The Imperial Gas-light and Coke Company were erecting, at their Hackney station, two gasometers of 10,000 cubic feet each, and about to erect four more of the same size. At their Pancras station they had marked out ground for six gasometers of 10,000 cubic feet each.”

The Report states, “that in the year 1814 there was only one gasometer in Peter-street, of 14,000 cubic feet, belonging to the Chartered Gas-light Company, then the only Company established in London. At present there are four great Companies, having altogether forty-seven gasometers at work, capable of containing in the whole 917,940 cubic feet of gas, supplied by 1315 retorts, and these consuming 33,000 chaldrons of coals in the year, and producing 41,000 chaldrons of coke. The whole quantity of gas generated annually being upwards of 397,000,000 cubic feet, by which 61,203 private and 7268 public or street lamps are lighted in the Metropolis. In addition to these great Companies, there are several private Companies whose operations are not included in the foregoing statements.”

Properties of different kinds of coal.

(823.) *Description of the process of gas making.*—It will have sufficiently appeared, from the preceding historical sketch, that great changes have taken place in the arrangement of gas Works, in the forms of the apparatus, and in fact in the general principle of the operation; but it will be unnecessary for us to enter here into an account of all these changes; it will be sufficient to explain to the reader the nature of the improved practice as it is now with little variation carried on in all our principal Works.

Mechanica.
Processes.

Processes
in the
making of
gas.

Manufac-
tures.

It will of course be conceived that, in so large establishments as the London Gas Works, different buildings must be provided for the different processes; viz. one for the retorts, called therefore the retort house, another for the condensing, another for the the purifying, &c. The gasometers are placed in the open air, and the whole must of course cover a considerable space, particularly as these separate buildings are frequently at some distance from each other. The reader must not therefore consider the plate we have given as exhibiting any actual establishment, but simply as a drawing intended to bring into one point of view the entire operation from the retort to the gasometers. In plate liii. fig. 1, we have endeavoured to give a connected view of the whole process, by referring to which the following explanation will be easily understood. A represents the fire-place or furnace by which the retorts containing the coal for distillation are heated, and *a, a, a*, show the retorts as they are arranged and set in the frame or oven of brick-work; our drawing represents five, but there may be more or less than this number. The mouth-pieces carrying the conducting pipes are screwed on air-tight, the top of these pipes are connected at top with a bridge-piece, and they then recurve and descend into the hydraulic main. The latter pipes are called dip pipes; they fall immediately behind the conducting pipes, so that their descent into the hydraulic main B cannot be traced.

The hydraulic main B is an iron pipe ranging the whole length of the furnace, and about 12 or 14 inches diameter; this is first about half filled with cold water, into which the dip pipes are inserted; but this water, soon after the process commences, is replaced by the tar and ammoniacal water deposited from the gas, and which as it rises above the level is carried off by the pipe to the tar vessel. The gas, descending first through the pipe *z*, is carried to the condensing vessel C, when it is made to pass through a succession of pipes, as will be more fully explained, in the course of which it deposits a further quantity, indeed nearly all its tar and other condensable impurities, which are first deposited in the lower vessel *i*, from which they flow as they rise into the tar cistern D, whence they may be afterwards drawn by cocks.

The gas now passes through the pipe *w* to the purifier, which is a close iron vessel containing lime water: it is divided by horizontal partitions into three chambers; within it are central cylinders open at bottom, but closed at top. The gas enters the lower one from the pipe *w*, into the central cylinder *p*, from which it escapes under the flanch *i*, and, passing through the pipe *v*, enters the second interior cylinder *q*, whence escaping again under the flanch *r*, it passes through the pipe *t* into the upper cylinder *s*, and thence through the pipe *u* to the gasometer F, where it is preserved for general use.

This description will be sufficient for the present. We shall now examine the apparatus and illustrate their use and intention more minutely, and shall also as we proceed point out some differences in them as they have been suggested by different gas engineers.

Nature and
product of
the coal.

(824.) *Properties of different kinds of coal.*—The raw material of coal gas is bituminous coal, of which there are two kinds; namely, that which when in small pieces, and thrown on an open fire, concretes into a mass by a sort of semifusion, forming cinder, and that which has not this coking property, but burns away to a white ash without yielding any cinder. If the only object of consideration in the selection of coal were the goodness of

the gas, *i. e.* the whiteness of the light which it affords on combustion, the non-coking coals would deserve the preference, especially those kinds that have a slaty structure, a grey rather than a full black colour, which do not soil the hands, and crackle when first thrown into the fire; such is the celebrated cannel coal of Lancashire, from the neighbourhood of Wigan and of Manchester, the splent coal from the collieries near Edinburgh, and an inferior kind of cannel coal from near Sheffield. But, as in all gas Works, especially those of London, and other places where coals are dear, the sale of the coke is looked to for reimbursing a considerable proportion of the cost of the coals, such must be selected as will yield a coke at the same time bulky and of good quality, the latter that it may fill well in the measure, coke being estimated by measure and not by weight. On this account the cannel coal of Sheffield, though it yields a large quantity of very good gas, yet because it does not coke in the retort, and comes out in smaller pieces than it went in, affords a perfectly unsaleable coke, and therefore is less profitable than the coking coals of Durham and Northumberland, though the gas from these latter is inferior both in quantity and quality. The market price of the coal is also a circumstance to be taken into consideration, for as the ultimate object of gas making, as well as of every other manufacture, is profit to those concerned in it, the seller will of course either raise the price or deteriorate the quality of the article which he deals in, as far as he can safely do so without hazarding the loss of his present customers, or diminishing his chance of gaining new ones. Whatever be the kind of coals selected for use, it is absolutely necessary that they should be quite dry, otherwise the retort will be cooled down by the conversion of part of the water into steam, while the other part by its decomposition will produce gases very injurious to the real coal gas.

(825.) *Of the retorts.*—The vessel in which the coal is decomposed, and the gas generated, is called, without much propriety, a retort; it consists of a cylinder, generally of cast, sometimes of hammered iron, of 6, 7, or 8 feet in length, and about 12 inches in diameter, and closed at one end. Five retorts are usually contained in one oven, being arranged in two rows; three in the lower one, and two in the upper: but sometimes more, and sometimes less are used; the flues of the oven being so contrived as to distribute the heat as equally as possible. In our drawing, these retorts, fixed in their places, are denoted by *a, a, a*, see plate liii. fig. 1. The advantages of the cylindrical form given to the retort are, that it is the least expensive, and that if it begins to wear away too rapidly in any one part, in consequence of its being exposed to a greater intensity of heat, the retort may be partly turned round, and the weak place thus removed from further injury. The disadvantage of the cylindrical form is that, when the charge of coal is put in, it is in the form of a segment of a cylinder, and consequently diminishing in thickness continually from the middle towards the sides. Now it is of advantage that the coal in every part of the retort should be acted upon as equally as possible by the heat, and with this view in many Works the cylindrical retorts have been replaced by those of an elliptical figure, the longest diameter being horizontal, or by four-sided ones, either plain, or with the edges flattened so as to make them octagonal, or finally oven-shaped, that is, flat at the bottom and concaved above. To each retort is attached a mouth-piece, also of iron, having a round hole at top to receive the end of

Mechanical
Processes.

Description
of the
retorts.

Manufac-
tures.

the conducting pipe, and capable of being closed in front by a plate of iron and a pressing screw. The proper working temperature is a cherry-red; when therefore the inside of the retort shows this colour, it is charged either by shovels, or by filling an iron scoop like a marrow-spoon with coals, thrusting it into the retort, and then turning it round; by this means the coals are of course discharged and the scoop is withdrawn, leaving the retort about half filled; the plate is then fixed to the mouth-piece without loss of time, and the gas is prevented from oozing out round the edge, by the application of lime-lute. The duration of a retort is very various, depending on a number of circumstances, but, accidents excepted, it hardly ever gives way in less than six months, and is often found to last more than double that time. The destruction of the retort goes on, at the same time, both from the outside and the inside; from the outside by the usual action of violent heat and air, from the inside by the reaction of the coal itself; in consequence of which the iron enlarges in bulk, and assumes the appearance of finely laminated black chalk, becoming at the same time quite soft and crumbly.

Each charge of coal continues in the retort six or eight hours, the latter being the most usual time. Even then the whole of the gas has not been driven out; but the rate of its production is so far diminished, and its quality is now become so far inferior to the average standard, that it is not worth while to carry on the process any farther. The plate which closes the mouth of the retort is therefore removed, and a volume of livid yellow flame pours out; the coke is withdrawn by means of long bars bent at their ends to a right angle, and as it falls from the mouth of the retort is extinguished by a pail or two of water thrown on it. The retort is now ready for a fresh charge.

Quantity
of coke ob-
tained.

The proportion of coke obtained from a given weight of coal varies considerably, according to the nature of the coal and the heat to which it has been exposed; and the quality of the coke is also affected by the same circumstances; a hot fire producing hard coke, a more moderate one a soft coke. From 22.5 to 34.5 per cent. will probably include the greatest and least loss of weight that coal undergoes by the process of distillation. If the coke is of good saleable quality, it usually, notwithstanding this diminution of weight, increases in bulk about one-half; 14 bushels of coal affording from 20 to 21 bushels of coke. The fuel used in heating the retorts is coke, and in some Works part of the tar is applied to the same use. The proportion of coke thus consumed is from 30 to 35 per cent. of the whole quantity produced. Let us now follow the course of the gas from the retort to the condensing main.

Progress of
the gas
from the
retort to
the con-
denser.

(826.) *Hydraulic main.*—On leaving the retort, the gas first enters an upright pipe called the conducting pipe, and deposits in it a quantity of hard pitchy matter, which would soon stop it up, if a bar were not thrust up it, in order to clear it whenever a new charge of coals is put into the retort. From the conducting pipe, it passes into a bent one called the bridge-piece, and then descends through the dip tube, which discharges it into the hydraulic main. In our drawing the dip tubes and bridge-pieces are hidden by the upright pipes above referred to.

After the retorts have been supplied with coals and heated as above described, the next object is to separate the different volatile substances which are in the first instance combined with the gas, some of which are separated by condensation, and others by a different process

which will be explained. To effect the condensation, Mechanical recourse is first had to the hydraulic main B. This is a Processes. strong cast-iron pipe of 12, 14, or more inches in diameter, and of the whole length of the several furnaces in which the retorts are worked. Its position requires perfect horizontality, and it is generally placed over and in front of the brick-work of the furnaces, and is supported by appropriate iron pillars. It has already been stated, that a pipe ascending from each mouth-piece of the retorts, of about 3 inches' diameter, and 4 or 5 feet long, is made afterwards, by recurving or by a bridge-piece, to descend again into the hydraulic main, where each pours its content of foul gas. As the principal purpose of this main is the condensation of the substances which the heat first expels from the coal, it is constructed so as to contain a quantity of cold water. One end of it is perfectly closed by a flanch, and the other has also a similar flanch, but a little above its horizontal diameter there is a pipe through which the water from the main first passes, and afterwards, as it is formed, the tar and ammoniacal water into a proper receptacle below; by this means the tar covered with a thin coating of the fluid is kept at a proper level in the main, the dip pipes being always immersed a few inches below the general surface. One great advantage attending this apparatus is, that by this means the pipe of each retort is insulated from all the others, so that when any one is opened it can only emit its own contents of gas, whereas if they were all in connection, there would be such a flow as would prevent the filling it again with coal. By the other pipe *z* the gas is conducted into the condenser.

(827.) *Condensing main.*—From the hydraulic main, Description of the con- the gas passes by the pipe *z* into the condensing main denser C, where it is cooled, and parts with nearly the whole of the tar and ammonia, and some other condensible impurities. The more perfectly the tar is separated, the more easy and complete is the subsequent purification, and therefore it is detained in the condenser as long as the necessary routine of business will allow. The usual form of the condenser is a rectangular vessel divided by two sets of partitions at right angles to each other, with two or three rows of cells, each row containing six or eight cells; the partitions do not descend quite to the bottom of the vessel, so that the fluids deposited in the different cells may be discharged into the tar cistern by a single pipe. The cover of each cell is pierced with two holes for the reception of an upright pipe bent double, one leg of each pipe being inserted in the cover of one cell, and the other leg in the cover of the adjacent cell; by which arrangement the gas passes through all the pipes and into every cell, and in this long transit cools down to the temperature of the air, and deposits nearly the whole of its tar and ammoniacal liquor, which are discharged into one covered pit, called the tar cistern, shown at D, the ammoniacal liquor occupying the upper part. Two cocks, or two pumps, a long and a short one, are fixed in the cistern, the former of which brings up the tar, and the latter the ammonia.

A still more simple form of condenser, proposed by Mr. Lowe, is merely a pipe with a number of ascending and descending bends in it, fig. 4. From the bottom of each bend descends a small pipe *a* bent up at the end, through which the tar and ammoniacal liquor are discharged; this affords an opportunity of procuring tar of two or three qualities, which may thus be applied to the uses most appropriate to each

Produce of
tar and
ammonia.

A chaldron of coals of average quality will give about $1\frac{1}{2}$ or $1\frac{1}{2}$ cwt. of tar, and from 15 to 18 ale gallons of ammoniacal liquor, and as the demand for these articles is very uncertain, they often accumulate to an inconvenient extent. Under these circumstances, part of the tar is usually employed as fuel in the retort house, and in some of the gas Works the ammoniacal liquor is manufactured into sal ammoniac, and other saleable forms of this alkali.

Process of
purifying.

(828.) *Description of the purifier.*—From the condenser the gas passes to the purifier E, where the sulphuretted hydrogen, and carbonic acid, and some other gases, none of which are condensable by mere cooling, are separated. The substance, by the chemical action of which the gas is purified, is lime usually mixed up with water to the consistence of thick cream. But, as a gas is not very readily cleared of any impurity by washing in a liquid, it is made to pass in succession through at least three purifying vessels, sometimes enclosed in one. These are covered air-tight cisterns of a cylindrical form, with an upright shaft in the axis, to which are attached arms or paddles for the purpose of agitating and stirring up the liquor, and thus preventing the lime from sinking to the bottom. The gas enters at the lower part of the purifier, and is first received under the flanch or umbrella-shaped plates, as already described, from the margin of which it is continually escaping in bubbles; these bubbles are again intercepted by a second plate, and thus fresh surfaces of the gas are continually exposed to the action of the lime liquor. From the first cistern the gas passes to the second, and from the second to the third. Here its purity, that is, its freedom from sulphuretted hydrogen, is tested, by letting out a little of it through a stop cock, and exposing to the jet a white paper moistened with a solution of sugar of lead. If the smallest portion of sulphuretted hydrogen remain in the gas, the paper will be tinged more or less brown; and, when this happens, the contents of the first purifier, that is, of the purifier into which the impure gas first enters, are discharged; and it is filled with fresh lime liquor and then receives the gas, after having passed through the two former purifiers; but as this cannot be done without a somewhat complicated arrangement of pipes and stop cocks, a simpler plan is adopted in some Works, by letting the contents of the second purifier into the first after the spent liquor has been discharged from that, and then letting the liquor of the third purifier into the second, and filling the third purifier with entirely fresh lime liquor.

The odour of the spent liquor is intolerably fetid, being a compound of that of sulphuretted hydrogen, tar, and ammonia. On the first establishment of gas Works in London, it used to be discharged into the drains, to the great annoyance of the whole neighbourhood; at present it is put into open vessels placed below the grate of the furnaces; here the watery part exhales, and, in so doing, greatly protects the furnace bars from the action of the intense heat in their vicinity; the residue of the lime liquor, now of the consistence of mortar, is partly used as lute for the mouths of the retorts, and what is not wanted may be carted away without inconvenience.

Another form of purifier, for which Mr. Phillips of Exeter obtained a patent, is to mix the lime only with such a quantity of water as shall bring it nearly but not quite to the consistence of mortar, or rather perhaps to that of moist sugar. This is to be spread on perforated plates, which are to be so arranged in boxes that the gas shall pass through the perforation, and thus be

VOL. VII.

brought in close contact with the lime. Two advantages are considered to attach to this plan, namely, that the necessity of subsequently evaporating the waste liquor is avoided, and the gas is presumed to be better, as retaining the whole of its olefiant gas, to which the whiteness of the flame is supposed to be owing, whereas the same gas being slightly soluble in water, it is to be presumed that more or less of it must be lost in the mode of purifying by milk of lime.

In this case the gas passes into and out of the purifier by a four-way cock, so that it may be sent either from the upper chamber downwards, or from the lower chamber upwards, a change which is necessary, because that platform of lime first acted upon by the gas will lose its power soonest; when this happens, the direction of the gas is reversed.

(829.) *Transmission of the gas to the gasometer.*—From the purifiers, the gas in many Works passes immediately into the gasometers, but in others it passes into a large revolving meter, described below, where it is measured by reading off the index, and the temperature is taken. These observations being made and registered at short intervals enable the superintendent of the Works to ascertain whether the retort men have been duly attentive to their business, and he is thus also informed of the total quantity of gas produced in 24 hours. This latter result may be more accurately obtained from the use of such a revolving meter than by a gage attached to the gasometer, affording, as it does, a more accurate correction for temperature. We shall describe this more particularly in a following page; it is merely alluded to here, as the apparatus is not shown in the drawing.

From the principal meter, when there is one, or from the purifier, when there is not one, the gas passes into the gasometer, or, more properly speaking, into the gas-holder. This is a hollow cylinder of sheet iron containing from 20,000 to 30,000 cubic feet. It is floated in a tank of water and is counterpoised by weights, the due proportioning of which adjusts the pressure on the enclosed gas, which pressure will generally be found to vary according to circumstances from half an inch to 3 inches of water.

Having thus traced the gas from the retort into the gasometer, this is the proper place to state the average quantity of gas produced from a given quantity of coals. This is usually estimated at 10,000 cubic feet for a London chaldron, but liable to variation according to the kind of coal operated on, and the length of time employed in distilling each charge. Some of the London Companies get, we believe, from certain Durham and Northumberland coals from 11,000 to 12,000 cubic feet, while cannel coal, even of an inferior sort, will yield as much as 14,000 cubic feet. Mr. Lowe's reciprocating retorts, in which the gas from each fresh charge passes over the red hot surface of the preceding charge, are said to yield from common coals far more than the highest of the above-mentioned numbers, in consequence of the decomposition of a large proportion of the tar, by the conversion of it into gas.

Instruments for measuring the quantities and qualities of the gas, for regulating the supply, &c.

(830.) In the preceding section we have endeavoured to give a general and connected description of the process of gas-making without interrupting it by any collateral details. It may, however, be proper to repeat again that the pipes through which the gas passes from the retorts to the

Manufac-
tures.

condenser, purifier, and gasometer, which, in our drawing, are all placed contiguously, may be at considerable distances from each other, and that, in the course of this tract, gauges are placed in different situations, so that, by turning a cock, the pressure of the gas in any of the pipes and vessels may be ascertained, any stoppages detected, and of course accidents prevented.

Another precaution against accident, and for announcing a stoppage in the pipes leading from the hydraulic main, is the application of a small gasometer at the other end of the main from that in which the gas and tar pipes are inserted; a small pipe from this end entering under the gasometer, in case of any stoppage in the pipes, raises the gasometer to a height proportional to the pressure, and when at a certain elevation it lifts a catch; this lets go a weight, which running down thereby rings a bell, announcing to the men on duty that a stoppage has taken place.

The next intermediate application is that of a stopcock, in immediate connection with the last chamber of the purifier; this being turned at any time, and the gas lighted and applied to the test-paper already noticed, will point out the state of the gas in this important stage of the operation.

Gas meter.

(831.) *Gas meter.*—In our Plate, the gas is represented as passing immediately from the purifier to the large gasometer by a short pipe or tube; but the gasometers are always at a distance from the purifiers, and generally the gas in its passage is made to pass through a large gasometer, by which may be ascertained the exact quantity of gas made in a given time. Some of these are sufficiently large to measure to the amount of thirty or forty thousand cubic feet per hour, and some of them have also an appendage by which they are made to register the number of feet made per hour, both day and night. In this form they are called tell-tales, but without this appendage they differ only in size from the smaller sort employed in private houses and establishments for ascertaining the quantity of gas consumed when the parties prefer paying at per cubic foot, instead of per burner. The same description will therefore serve for both; it is, however, although very simple in its operation, rather complicated in its construction, and the following description is intended rather as explanatory of the principle of the instrument than of the instrument itself, which indeed has been considerably changed in form since it was first projected by Mr. Clegg.

In plate liii., fig. 2 and 3, we have given two sections of this instrument at right angles to each other; *c c c* is a close hollow drum, one face being removed to show the four partitions in it; at the centre there is a hole pierced through both sides or ends of the drum; *d d d d* is an interior drum having partitions in it, shown in fig. 3. This interior drum turns on an axle *i*, the axle passing through the bar *m m*; *a* is the pipe by which the gas enters into the Machine, and *h* that at which it escapes after its measure is ascertained, in the way described below; the four compartments *t t t t*, into which the interior drum is divided, communicate, by holes or slits *b b b*, fig. 3, with the hollow in the centre, where the gas is first let in; they have no direct communication with each other, but are connected with the outer space by the holes *e e e e*. This inner cylinder turns freely on the axle running through *i*, being fixed at one end to the cylinder, and at the other kept steady by the cross bar. This end of the pivot does not reach to the outside of the cylinder, but is inserted in a

hole drilled in the side of the pipe *a*, which enters the internal cylinder. The other end projects from the inner cylinder, and reaches through the hole in the outer cylinder to a tin cup, *n n*, in a hole of which it turns. Within this cup a cog-wheel is fitted to the pivot, but not shown in the figure, by which its revolutions are recorded on the face of a dial by the aid of clock-work. Water is poured in at a small pipe in the outer cylinder at *n*; there is also another pipe or opening at *k*, whereby the water escapes when it has attained its proper level, which is thus insured; both openings are then closed by screw stoppers, and the Machine is now ready for use. The operation of this ingenious instrument will be easily comprehended if the foregoing description has been well understood. The gas to be measured is admitted through the pipe *a*, which is bent upwards, so that its orifice is above the level of the water. The small portion of the central hollow above the water is soon filled, the gas then flows through *b* into that division which is almost all under water; this in the figure is on the left hand, marked *t*. The pressure of the gas on the surface of the water forces that division to rise, and, consequently, the whole internal cylinder to turn round. When this division is quite full of gas, the hole *b* will be just dipping under the water, and water will flow into it instead of gas. At the same moment, the slit *e*, by which the division communicates with the outer cylinder, will rise above the water, and the gas will flow out as the water enters the hole *b*. The next division will then be filled in the same manner, the inner cylinder, with its pivot and the cog-wheel attached, will continue turning round, and the gas which has passed through it will leave the Machine through the pipe *h*. It is now clear that in one turn of the inner cylinder as much gas will pass through the meter as is sufficient to fill up its four compartments; and if that quantity be known, it will be easy to arrange a piece of clock-work, attached to the Machine, so as to point out on a dial the actual number of cubic feet that has passed through it.

(832.) *Of the supply of gas.*—The gas is discharged from the gasometer into the distributing mains by the pressure exerted on it by the weight of the gasometer itself, adjusted by the counterpoise; but the variations of pressure in the main itself depend on the due regulation of the valves which command the communication between the gasometer and the main; in this case, therefore, a high pressure indicates a copious supply, and a low pressure a smaller supply. During the day, no greater supply of gas is wanted than is necessary to be an equivalent to the loss from leakage, otherwise atmospheric air would find its way into the pipes, and might occasion explosions. But as evening draws on, the lamps, both public and private, are lighted, and therefore a full supply of gas is required. After nine o'clock, some shops are shut up, and therefore the consumption of gas is diminished; at a later hour more lamps are put out, and at dawn the public lamps also are extinguished. Now that there may be no deficient or redundant supply, during this time, great care on the part of the person entrusted with the valves is required, and the accuracy with which he performs his duty is shown by the Pressure Indicator, which was invented by Mr. Crosley. It consists of a small gasometer, the interior of which communicates with the gas main by a small tube. An air vessel within this gasometer makes it float when down at its lowest immersion, so that in this situation its interior is in equilibrium with the atmospheric pressure, and

Mechanical
Processes.Pressure
Indicator.

Manufac-
tures.

by increasing the pressure on the gas in the main, the pressure on the air in the gasometer is equally increased, and thus the gasometer floats higher. This variation of height is estimated by a scale divided into inches and tenths. The guide rod of the gasometer has a spring pencil-holder attached to it, adapted to press the point of the pencil against a piece of paper divided vertically into heights, and horizontally into intervals of an hour each. The cylinder moves on its axis at a given rate, being connected with a time-keeper, and thus the variations of pressure, as indicated by the pencil attached to the gasometer, are also connected with time by means of the revolving cylinder.

Gas go-
vernors.

(833.) The *gas governor* is an instrument, invented by Mr. Clegg, for regulating, like the last, the inequalities arising from the irregular pressure of the gas-holders, as well as from the putting out of the lights at different periods of the night. This contrivance consists of a small gasometer of sufficient weight for producing the required pressure; the interior of it is in direct communication with the pipe through which the gas passes. This gasometer is connected with a regulating valve, so that when the pressure, at any time, increases, the gasometer rises and contracts the opening; and, on the contrary, if the pressure diminishes, the gasometer falls and increases the opening. In every case, the aperture is always in unison with the demand, preserving the flame at one uniform height. Its purposes are more effectually accomplished by placing one, on a small scale, in each house; but one on a larger scale, placed at the main outlet at the gas Works, will equalize the general pressure, and seems to be absolutely necessary where governors are not individually used. This is a self-acting Machine, and requires no alteration when once adjusted. The following description will probably render it intelligible:

Pl. liii.
Fig. 5.

Fig. 5 is a section of the governor, and A B C D exhibit the outer case; this is made of sheet iron or copper, with the top and bottom closed, and both the inside and outside are also japanned; *a b c d* show the form of the small gasometer, *e f* the pipe through which the gas enters, and *g* the pipe by which it passes out. The conical valve attached to the bottom of the upright spindle rises or falls so as to contract or enlarge the aperture E, as the gasometer ascends or descends by the entrance or passing out of the gas, and F G is a short hollow cylinder or cup in which the outer case is fixed at the centre of its base. Mr. Crosley has made some improvements in the construction of the governor for regulating the supply at the main outlet of the Works, so that by its own action the pressure is increased or diminished with the quantity supplied. One of the modes he employs is in the construction of the small gasometers. Some years back, by making an experimental gasometer on a small scale, and requiring uniform pressure for comparing the intensities of light, instead of using, as heretofore, a compensating chain, which it was not easy to make free from friction, he found that he could effect the same in a more simple way by making the gasometer less in diameter at the top than at the bottom. Hence, by increasing this difference, the gasometer may be made to vary its pressure to any required degree. He also effects the same purpose by employing a gasometer of the common construction, making the necessary compensation by means of a cycloidal wheel, over which the balance-weight is suspended. This wheel is formed with moveable pegs

for varying the curve, and adapting it at pleasure to any required variations.

By certain modifications of the governor, Mr. Crosley has rendered it capable of regulating the discharge of gas from a portable gas vessel, so that, without any adjustment of the valve, the flame is preserved uniform from the beginning, through all the variations of pressure, from thirty atmospheres down to that of common gasometers.

(834.) *Apparatus for registering the impurities of gas.*—This is also a simple but very ingenious instrument of Mr. Crosley's invention, intended for indicating and registering the impurities of the gas, and which, at the same time, denotes the periods when they occur.

The arrangement of this apparatus consists of a circular card placed upon an axis, which communicates with a time-piece. Upon this card three circles are described, which are divided into 24 divisions by lines drawn from the centre, corresponding with the hours of day and night. The two largest circles, which are of equal breadth, occupy the marginal space at the outer extremity of the card; these are coated with the usual solutions or tests for sulphuretted hydrogen and ammonia, and a very small jet of gas, from an orifice adapted to each of the circles, is made to play constantly over them. The inner circle being divided into spaces that are marked from 1 to 12 for *day*, and 1 to 12 for *night*, hence, as the axis of the time-piece performs its revolution with the card attached to it, the *impurities*, and the *time* when they happen, become exactly registered: and by changing these cards daily a perpetual register is obtained. The principle on which it acts renders the managing of it readily attainable; and its utility is so obvious, that perhaps it will eventually come into general use.

(835.) *Instrument for ascertaining the specific gravity of the gas.*—This is an exceedingly simple instrument. It in some measure resembles in form a small flask, with an opening and cap at each end, which may be completely discharged of the air, and filled with gas, by placing one of its ends upon a pipe or cock, of the same size, and passing a current of gas through it in the following manner. A projection is placed on each side of the flask, by which it is intended to be held in the hand, so that the temperature of the gas or air within may not be increased.

Previously to the flask being filled with the gas intended to be weighed, let it be freed from foul air or gas, by taking off the caps from each end, and passing a current of fresh air through it, until the air within is the same as without; this may be easily effected by moving it quickly and repeatedly to and fro, endways, in the air; the caps may then be put on, and the flask accurately balanced; this being done, take off the caps, and pass a current of gas through it during about ten seconds of time; then put on the cap at the upper end, and, at the instant of disengaging the bottom end of the flask from the pipe or cock, put on its cap, and immediately weigh it again, when the diminution or counterweight, required for restoring the balance, will be a datum for determining the specific gravity of the gas.

Namely, as the weight of the air is to the weight of the gas, so is the specific gravity of the air, which is taken at 1000, to the specific gravity of the gas. In order to facilitate the computations there is sold, with the instrument, a table containing the weight of 50 inches of air in grains for all the usual barometric pres-

Mechanical
Processes.

Apparatus
for ascer-
taining the
state of im-
purity.

For deter-
mining the
specific gra-
vity.

Manufac-
tures.

tures and temperatures. The rule therefore is, from the weight shown in the table for any given pressure and temperature, subtract the counterweight above referred to; the remainder is the weight of the gas. Divide this remainder by the tabular weight, and the first three figures will be the specific gravity of the gas, that of the air being 1000.

Oil Gas.

Process of
making oil
gas.

(836.) We have in the above notice confined our account of gas-lighting to that of coal gas only; but our Treatise would be incomplete if we did not slightly allude to the attempt made for substituting oil gas for coal gas, but as it may be said to have been, if not a failure, yet certainly not attended with all the advantages the projectors anticipated, a very little illustration of the principle of operations will be sufficient. The light from oil gas is generally admitted to be more pure than that from coal gas, particularly as the latter was manufactured in the year 1815, the period at which the patent for oil gas was obtained; and its purity and freedom from the bad smell which attended the former gave it a preference for private houses. In point of economy, however, it had no chance with coal gas, and it is at this time, we believe, scarcely any where employed. The process of making it, as recommended by Messrs. Taylor and Martineaux, will be understood from plate liii., fig. 6.

Pl. liii
Fig. 6.

Here A represents a section of the furnace or oven for heating the retort to a red heat. The front of the retort, which is a cylindrical cast-iron vessel, is shown at B, the mouth is fitted with a cover to completely close it as in the coal gas retort, and it is partly filled with coke and broken bricks, so that the oil which falls by drops upon the heated substance may be exposed to as large a heated surface as possible, in order the more completely to decompose it and convert it into gas.

C is a section of a copper vessel to contain the oil, which, by means of a cock *a*, is allowed to drop regularly through the pipe *b b*, upon the heated matter in the retort, where it is decomposed and converted into gas and other volatile products, and these pass along the pipe *c* into the square cistern or condenser D. This condenser consists of two iron vessels, one within the other, and the space between them is filled with cold water, in order to keep the inner one cold, and thereby to condense the products of the distillation as they pass through it. The oil which the heat may convert into vapour without decomposition, condensing again into oil, forces through the pipe *d*, and again enters the oil vessel C, to be with the other contents again submitted to the retort.

But the gas ascends through the pipe *d* to the purifier E, which is filled with oil nearly to the top, and a board is placed obliquely across it, that the gas, by entering at the lower end, may have to pass over a large surface of the oil, and become thoroughly washed before its transit through the pipe *f* to the gasometer. The upright pipe *g* preserves the oil at an equal height in the purifier, and the funnel *h* is for supplying the oil vessel. The use of the cock *i* is for drawing off any water that may mix accidentally with the oil.

F F represents the cast-iron stand which supports the condenser, purifier, and oil vessels. The gasometer is not shown. It, of course, is similar to that above described for coal gas.

Portable
gas.

Portable Gas Vessels. The gas obtained, according to the principles last described, from oil, possesses, as we

have stated, a greater degree of purity than coal gas, and, consequently, affords a greater degree of light according to its bulk, and, therefore, a less quantity of it and smaller burners are required for a given amount of illumination. This property led to the idea of moveable or portable gas vessels, which, in some cases, have been found very convenient. Portable gas consists of oil gas greatly compressed and forced into strong wrought-iron vessels, which are made of various dimensions according to their intended purpose, and of various forms, many of them highly ornamental.

Mechanical
Processes.

For common purposes, where ornament was not studied, they were commonly cylindrical with hemispherical ends, with an opening fitted with a valve at each end, one for admitting the gas, and the other to supply the gas for consumption.

A Company was established in London, called the Portable Gas-light Company, having for their engineer M. D. Gordon, the inventor of this species of gas-light, who supplied private families with their gas at a certain price per foot, sending round at certain periods for the vessel, and returning it filled with gas compressed about thirty times.

This high pressure it is evident required vessels of great strength, and perhaps, after all, it required some practice before a person or a family could sit down without apprehension to a light proceeding from a vessel on the table before them, so highly charged that any fall, flaw, or accident, would expose them to the most serious disaster. Great precautions were, therefore, taken by the proprietors to have their vessels submitted to a severe proof before they were filled with gas for use, and we are not aware of any accident from explosion having occurred. The price at which the gas is served to the Public is 6s. 3d. for 100 cubic feet.

We have been greatly indebted in the writing the preceding sections to various Papers in different Philosophical publications, to the *Phil. Trans.*, to an ingenious and useful Work by Mr. Packston, and particularly to two Works by Mr. Mathews, one on the History and another on the Practice of the Art. We are also much indebted to Arthur Aikin, Esq., Secretary to the Society of Arts, for the use of a MS. he had compiled for a Lecture at that valuable Institution.

Lighthouses.

(837.) Amongst the Works of public utility which are intended to be treated in this Division, there are few of greater importance to a maritime power like Great Britain than Lighthouses, whether they be considered with reference to the immense value of the merchandise which is thereby protected from destruction, or to the many lives which, without such guides, must inevitably be annually sacrificed on a sea-girt coast like that of England. These circumstances, and the very large revenue and expenditure of the Lighthouses on our shores, have on different occasions attracted the attention of Parliament. During the last year (1834) a long and laborious investigation of the subject took place before a Committee of the House of Commons, and a Report, with the Minutes of the evidence, has been recently printed by order of the House in a large volume, from which we intend to abstract briefly all the more important and interesting particulars. The construction of Lighthouses has already been given in our alphabetical arrangement, so that in the present notice it will only

Manufac-
tures.

be necessary to treat of what may be called the statistics of the subject, and to give an account of the experiments which have been made with a view to improvements in the system of lighting, which, although very considerable within the course of a few years, it is very desirable to extend still further, by availing ourselves of all the advantages furnished by the various and valuable discoveries in Chemical, Optical, and Mechanical Science. It will be well, however, before we enter upon a description of these experiments to show the great extent of the present system, the nature of the lights, the consumption of oil, &c., the revenue derived from light and beacon dues, and the application of the funds thus arising.

By whom,
and by
what
authority,
erected.

The erection of public Lighthouses in England has been undertaken either by individuals, or by the Brethren of the Trinity House, to whom patents for the purpose have been granted by the Crown, on the presumed general wish of those interested that the same was necessary, and would be useful; and petitions from merchants and shipowners have generally been presented at the same time to the Crown, offering payment of certain tolls or dues for the maintenance of such lights when erected.

The public general lights of Scotland are under the management of a Board, denominated the "Commissioners for Northern Lighthouses," incorporated as such by the 38 Geo. III. c. 58; and the Commissioners hold their office at the Board by virtue of the public situations they fill. They are twenty-five in number, and, with the exception of the Lord Advocate and the Solicitor-General for Scotland, are all municipal offi-

cers. Their services are gratuitous. They have no power to interfere with any of the local or harbour lights.

The lights of Ireland are under the superintendence of the Ballast Board, a Corporation consisting of twenty-three Members, who are the Lord Mayor and Sheriffs of Dublin, three Aldermen, chosen by the Board of Aldermen, and seventeen other individuals, appointed in the first instance by the act of incorporation, but who have the power of filling up the vacancies.

The public general lights of England are seventy-one in number, including one on the Island of Heligoland, off the coast of Holstein. Fifty-five of these general public lights belong to the Corporation of the Trinity House, Deptford Strond, the revenue from them being managed for the benefit and objects of that Institution. Three have been leased by the Trinity House to individuals, seven have been so leased by the Crown, four are held under patents subsequently sanctioned by Acts of Parliament, and two are under the management of the Trinity House, but the deficiency of the dues at one (Heligoland) is made up by Government, and the other is supported by the Admiralty.

The following is a statement of the lights belonging to or under the management of the Trinity House of Deptford Strond, distinguishing whether fixed, revolving, or floating; showing the number of burners in each, the annual consumption of oil, the number of keepers, with their salaries and allowances; the tonnage of the light vessels, the number of the crew of each, their wages and allowances; together with the salaries allowed to the agents of the respective establishments. February, 1834.

Amount of revenue.

(839.) In other Tables given in the Report the amount of revenue derived from the several lights is given, and the charges thereon, the surplus and other particulars; not only in those under the management of the Trinity Board, but also of private persons, the Commissioners for the Northern Lighthouses, and the Ballast Board, of which the following is an abstract.

No. of Lights.	By whom held.	Gross Collections.	Charges of Collection.	Expense of Maintenance.	Net Surplus.
		£	£	£	£
55	Trinity House . . .	83,041	6,670	35,904	40,467
14	Private Individuals	79,676	10,244	9,109	60,322
25	Commissioners of Northern Lights	35,526	3,261	11,314	20,051
40	Commissioners of Ballast Board, Ireland	42,061	1,960	18,505	21,596
134		240,304	22,135	74,832	142,436

Appropriation of the revenue.

(840.) Referring only to the Trinity Board, it appears that after defraying the necessary expenses, a large surplus annually accrues to the Corporation of the Trinity House out of the rates collected from the shipping for the support of the Lighthouses. A considerable portion of this surplus is devoted to charitable objects, the promotion of which is deemed by the Board one of the duties imposed on them by their Charter. A question has, however, arisen whether dues can be levied on shipping for any other purpose than that of supporting the Lighthouses, &c. The General Shipowner's Society in London, the Chamber of Commerce in Greenock, and others, object to such large sums being applied to charity, and call for relief to the shipping by a reduction of dues. Select Committees of the House of Commons, in the years 1822 and 1824, recommended to the Brethren of the Trinity House to reduce their expenditure for charitable purposes, and to lessen the amount of the imposts and restrictions on the shipping. But the Brethren have

not deemed it their duty to attend to these suggestions; for in the year 1820 their expenditure on the almshouses and pensioners of the Trinity House amounted to £32,035, and in 1832 to £32,861. The present Committee are, however, strongly impressed with the justice of limiting the charges upon shipping, in every case, to the purpose for which the charges are sanctioned, whether by Patent or Act of Parliament; and if there should be a surplus, that a reduction in the amount of these, and all other rates, should be made equal to the whole surplus. No objection is made by the Committee to the present mode of appointing the objects of charity, or to the manner in which the bounty is dispensed; the objection is to the *principle* of taxing the shipping for any other purpose than that of supporting the Lighthouses. The Select Committee on Foreign Trade in 1822 questioned the right as well as propriety of applying the surplus light dues to the purposes of charity; and in examining into the 36th of Elizabeth and the Charter of James II., by which the Trinity dues are regulated, they reported, that "no specific appropriation of these dues is to be found, except what may be collected from the 62d section of the last-mentioned Charter, which directs the application of moneys received by decrees, orders, agreements, fines, forfeitures, or otherwise, to the repairing of the Trinity almshouses and the relief of poor Brethren and their wives, and poor seafaring men." The charge made on foreign ships, it is stated, does not appear to be authorized by any Act, Charter, or Patent; and the amount on British shipping exceeds considerably the rate sanctioned by the Charter under which it is collected.

"It may even be conceded," the Committee observes, "that the surplus dues from the buoys and beacons, and the rent of land, might be applied to charity; but if the whole surplus from all these sources be applied to pay a just proportion or share of the expenses of the salaries of the Elder Brethren, and of the office establishment, there will be no surplus whatever for such charitable purposes."

On a review of the evidence relative to the right of the

Manufac-
tures.

Trinity House to retain a surplus arising from the light dues for the purpose of being applied to charitable objects, the Committee, after mature consideration, and referring to the Reports of the Select Committees of 1822 and 1824, recommend that all pensions and charitable allowances now paid by the Trinity Corporation from the surplus of the light dues under their management (except to servants and others belonging to the lighthouse establishment) shall cease with the lives of the individuals now on the pension list, so far as the same may be legally done; and that from and after this time no new pensions, save as above excepted, shall be admitted on, or paid out of the surplus of the Lighthouse dues." And in the event of the Trinity House Brethren not deeming it to be their duty to attend to this recommendation, it is stated that "it is in the power of his Majesty in Council, by the 3d Geo. IV. c. 3, to require a reduction in the rates, prices, dues, duties, or tolls, imposed or granted by any Charter or Act of Parliament to the Trinity House;" "and if the Board," it is added, "should persist in applying the surplus light dues to charitable purposes after the House shall have decided to adopt the recommendation of your Committee, it will be easy for his Majesty in Council to require the Board to reduce the dues on each or on all these sources of income, until the Trinity Board shall not have any surplus to apply."

In order to form a correct opinion of the reduction that might have been made, or may now be, the following comparison is given of the clear income and expenditure of the Trinity House in two different years:—

	1820.	1832.
Amount of surplus for general purposes, arising out of light dues. .	£51,561	£40,467
Surplus of buoyage and beaconage. .	2,769	3,643
Net profits of ballastage	1,962	2,185
Interest on stock in the public funds	6,960	4,781
Rents of estates for charitable uses.	2,316	3,797
	£65,568	£54,873
Expended on almshouses and pensioners	£32,035	£32,861
For salaries, office expenses, &c. . .	12,149	16,725
For new lighthouses, &c.	15,223	21,868
Cash vested in public stock	2,000	
	£61,407	£71,454
Balance in hand	£4,161	
Excess of expenditure		£16,581

The excess of expenditure in 1832 was augmented by the purchase of the North Foreland lights.

The Trinity House have at present a sum amounting to £155,873, arising from the surplus dues of former years, invested in the public stocks, yielding a yearly interest or dividend of £4676, applicable to the general purposes of the Corporation, and exclusive of those sums which are invested for particular charitable purposes under the management of the Board. Though the Brethren declined to attend to the recommendation of the previous Committees, and have intimated to the present Committee that the same disposition still prevails, "and that they are not disposed to reduce the charity they now dispense," they have reduced the rates formerly charged on all shipping for the objects of their institution. Since January, 1823, "one penny per ton has been charged on British oversea traders, and on

foreign privileged vessels entering the port of London, instead of eightpence formerly charged; and foreign vessels not privileged have been reduced from eightpence to twopence per ton." The benefit of this reduction may be estimated by the fact, that the toll levied on the shipping in 1832 for 55 lights was less by £7998 than the toll levied in 1820 for 33 lights.

(841.) Such being the great revenue derived from the lighthouses of Great Britain, it is very desirable that every aid that Science can afford should be had recourse to, in order to render the system the most perfect and efficacious possible; and it is admitted by the Committee that every readiness has always been shown by the Trinity Board to effect this great object. Accordingly, numerous experiments have been made with gas of different kind, with lenses, and by other means, on which most interesting information is given in the Report and in the Minutes of Evidence. Of these, the first question is the nature of the light. It is not many years since the lights were produced merely by coal fires, unaided by any optical or other means; then were substituted tallow or wax candles, also unaided by reflectors or otherwise. At length, Argand invented his celebrated burners; these were soon after employed with parabolic reflectors, placed behind to reflect the light; and many lights were substituted for one larger, because the reflector of course intercepted all the light, except that falling on its reflecting surface. This is now the light generally adopted; and although it is very desirable to increase the focal light, there is perhaps no other Mechanical or Optical arrangement so well suited for the purpose. The reflectors at present used have certainly not the most perfect surface, as they consist only of copper plated, and their curvature is given only by the coppersmith's hammer, or by some similar means; they, therefore, are necessarily but imperfect reflectors, and probably do not throw back more than one-third the light falling upon them; but on the other hand they intercept a large portion of the sphere of radiating light from the burner, probably three-fourths of the whole, and, if so, three-fourths of one-third of the entire light, or one-fourth of the whole is projected in the line or cone of reflection.

The quantity of light, however, absorbed by the reflector has been thought objectionable, and this led in one or two cases to the application of a lens on the principle of refraction. But here two sources of loss were substituted for one. The portion of the radiating sphere of rays, intercepted by the lens, was scarcely one-twentieth of that intercepted by the reflector; and, moreover, the thickness of glass absorbed a great portion of the light that fell upon the refracting surface; so that upon the whole such a light was very inferior to the former.

This latter objection was obviated by an ingenious suggestion of Sir David Brewster, which consisted in forming what he calls a polyzonal lens. Instead of a large solid lens of 3 feet diameter and 3 feet focus, in one mass, he suggested the idea of building one of the same dimensions in several segments, preserving the refracting surfaces, but avoiding the thicknesses on the central parts. The lens, a section of which is shown in plate lvi. fig. 7, 8, was executed by Mr. William Gilbert, optician, Leadenhall-street, London, and on several occasions the writer of this Paper had opportunities of witnessing its effect, both with the maker individually, and with the Elder Brethren of the Trinity House.

Drummond's light.

Subsequently, a much more elegant and effective means of lighting was suggested by Lieutenant Drummond, of the Royal Engineers, which consists in the combustion of streams of oxygen and hydrogen on a ball of lime placed in the focus of a common parabolic reflector, the light from which is so intense as to cast a shadow on the ground at the distance of 12 or 15 miles; being equivalent in power to 240 Argand burners. A particular description of this light and apparatus is given in the *Philosophical Transactions* for 1830, from which, and from the Minutes of Evidence, above quoted, we shall select a few particulars; only observing that, at a trial of the effects of the three lights in one of the long storehouses in the Tower, the writer was present, and he cannot better state the comparative effect of the three on his mind than by saying, that supposing Lieutenant Drummond's light to be the sun, Sir D. Brewster's lens was comparatively the moon, and the common reflector and Argand burner a watchman's lantern. On these comparative effects, however, the Report has entered at some length, and we cannot do better than give it in the language of the reporter.

Parliamentary Report. Lieutenant Drummond's evidence.

(842.) Lieutenant Drummond, being requested to state to the Committee the result of his observations on the different modes of lighting Lighthouses, replied, that "the mode now in use in this Country consists in placing the common Argand burner in the focus of a parabolic reflector. This instrument is made of silver, strengthened with copper; it is about 3 or 4 inches in focal length, 21 inches in diameter, and is in general use in the Lighthouses of the United Kingdom; the number and arrangement of the reflectors in each Lighthouse depend on the light being fixed or revolving, and upon other circumstances connected with the situation and importance of the Lighthouse. The mode adopted in France consists in placing a large Argand lamp, having four concentric wicks, and giving a very powerful light, in the centre of the building, and around it a series of glass lenses of a peculiar construction; using in this case a refracting instead of a reflecting instrument, to collect the light, and only one lamp instead of a number. The lens is a very beautiful instrument; it is about 30 inches square, plano-convex, and formed of separate rings or zones, whose common surfaces preserve nearly the same curvature as if they constituted portions of one complete lens, the interior and useless part of the glass being removed. To form a lens of such magnitude out of one piece of glass would scarcely be possible, and, if it were so, the thickness of the glass would materially obstruct the light. The merit of the invention consists in building it of separate rings. The priority of the suggestion is due to Dr. Brewster; MM. Arago and Fresnel subsequently proposed the same plan, manifestly without the knowledge of what Dr. Brewster had done; and they were the first who got such a lens constructed, and who showed, that when used with the powerful lamp alluded to, it might be applied with great advantage and effect to the illumination of Lighthouses."

Examination continued.—"What is your opinion on the relative merits of the two modes which you have stated?—The light given by the lens was found by our experiments at the Trinity House, in London, to be equal to that of 9 common reflectors.

"One lens?—Yes; the light of one lens equal to the light of nine reflectors. Then there is some additional apparatus described in the Memoir of Fresnel, and used

at the Carduan Lighthouse, but which we did not possess, which is said to increase the light so that it may be taken to be about equal to the light of 10 reflectors.

Mechanical Processes.

"That is, an increase of one light?—Yes.

"What is the nature of that additional apparatus, by means of which this additional light is obtained?—The nature of the apparatus is this: that portion of the light of the lamp which escapes the lens placed in front of it is caught by another and smaller lens placed above it, and then again reflected in a horizontal line parallel to the beam of the original lens.

"Then it appears to be a small additional lens, a refractor to throw the light back on the lens?—It is rather difficult to explain this without a diagram. This additional refractor would throw the light which it collects in a beam diverging from that of the first or primary lens: this secondary beam must, therefore, be again bent down and thrown in the direction of the first beam; this is effected by plane reflectors. The escape of all that light which passes above the primary lens is thus prevented, but its brilliancy is considerably diminished by the complexity of the reflecting and refracting apparatus; it may, however, be considered as contributing, in the proportion already stated, to the original light; and, therefore, one of these lenses, with the apparatus complete, as used in the French Lighthouse, may be considered, according to our experiments, equal to 10 of the common reflectors.

"What is the comparative expense of oil between the two?—The result of our experiment was, that the French lamp consumed as much oil as, I think, 17 lamps.

"One of the French lamps?—Yes.

"Consumed as much as 17 Argand lamps?—Yes; and that I think is very nearly the same result which MM. Fresnel and Arago have given; but I state this from memory.

"Giving the light of only ten?—Yes.

"Then, if the consumption of oil in the Carduan Lighthouse is as 17 to produce the light of only 10, wherein is the advantage of using such lamps in preference to the plain burners?—I stated that the lamp was placed in the centre of the building, and the lenses placed round it; each of the lenses occupies a portion of the circle equal to 45 degrees; so that eight such lenses may be placed round the lamp to complete the circle. In an English Lighthouse of the first order, take Beachy Head for example, the most recent, and justly considered one of the best, there are 10 reflectors on each side, and there are three sides illuminated; so that there are 30 reflectors in all, and of course 30 lamps. By a consumption of oil, therefore, equivalent to that of 17 common lamps, an effect is produced in the French Lighthouse equal to that which is produced in the English Lighthouse by the consumption of 30 such lamps.

"That is, one French lamp, applied in that manner, will give you the same light at the expense of 17, which the 30 reflectors do at the expense of 30?—Yes.

"And the light would be total in the one case, whereas the other is only on three sides?—In the one case you have three sides, and in the other case you have eight sides illuminated. But there is a circumstance, not unfrequently overlooked, which must here be taken into consideration, and that is the divergence of the light, which is different in the two cases. In the

Manufac-
tures.

common parabolic reflector the divergence is equal to about 17 degrees; in the French lens it is equal to rather more than 5 degrees; so that in the English Lighthouse 3 times 17 degrees will be the total illuminated portion in one revolution, and 8 times 6 will be the illuminated portion in the French during the revolution.

"Then are the Committee to understand that the light from the French lamp diverging only 5 degrees is much more intense than when by the English reflector it diverges 17, and, consequently, will be much better seen, although perhaps not so long?—When both are directly opposite to the spectator, he would not be able to distinguish any difference between the 10 reflectors and the French lamp, but the period during which each side would be visible would be greater in the English than in the French. It will be recollected, however, that in the French there are eight sides illuminated, whereas there are but three in the English.

"In short, the English illuminates more of the sea?—Yes; comparing with the side. During one revolution, say of seven minutes, there would be in the English Lighthouse three equal periods of light, each lasting 20 seconds, separated by equal intervals of darkness, each lasting 120 seconds. In the French, eight periods of light, lasting each about 6 seconds, with intervals of darkness, each lasting about 46 seconds."

Drum-
mond's
light and
apparatus.

Pl. lvi.
Fig. 1—6.

(843.) *Drummond's light and apparatus.*—We proceed now to explain the apparatus employed by Lieutenant Drummond for fitting his light to the purposes of the Lighthouse, taking our description from the *Philosophical Transactions* for 1830. In our plate, (marked lvi.) fig. 1. represents the lamp. The two gases, oxygen and hydrogen, proceeding from separate gasometers, enter at *o* and *h*, but do not mix till they arrive at the small chamber *c*, of which fig. 2 is a section: into this chamber the oxygen gas from the inner tube is projecting horizontally through a series of very small apertures, and the hydrogen gas rises vertically through a series of similar apertures at *d*. The united gases then pass through two or three pieces of wire gauze placed at *e*, and, being thus thoroughly mixed, issue through the two jets against the ball *b*. To prevent the wasting of the ball opposite the two jets, and at the same time to diffuse the heat more equally, it is made to revolve once in a minute, by means of a movement placed underneath the plate *m*, and with that the wire *f*, carrying the ball and passing through the stem, is connected. Notwithstanding, however, this arrangement, the effect of the heat is such as gradually to cut a deep groove in the ball, so that at the end of about 45 minutes it becomes necessary to change it. In a Lighthouse, where it is of essential consequence to maintain a constant light, it would be unsafe to intrust this to an attendant, and hence the necessity of devising some means for remedying this inconvenience. The apparatus represented by fig. 3 is designed for this purpose, and is drawn in the manner in which it is applied to a reflector, the dotted outline of which is shown.

The wire *a b* passes through the focus of the reflector, and upon it are placed the number of balls, at *A*, required for any given time; these, by means of the shears *s*, as shown in fig. 4, are admitted between the plates *p p*, and hence permitted to fall in succession to the focus. No. 1 represents the focal ball; about two minutes before the change, the ball 3 falls into the position 2, where it becomes gradually heated. At the end of that

time the curved support *t*, moving on a pivot, is thrown into the position represented by the dotted line, by the momentary descent of the ring *r*, which, receiving an impulse from the weight *w*, acts upon the extremity *u* of the support. No. 1 falls, but it is prevented from descending more than its own diameter by the loop *l*, and No. 2, following it, occupies the focus. The support *t*, being immediately released, returns by the action of a spring to its former position, retains No. 2, and suffers No. 1 to escape through the loop into the cistern.

The wire *a b* and the support *t* revolve together, and carry round the focal ball, which is ignited as in fig. 1 by the two jets *z z*. These jets, which are movable round the joints *d d*, enter through small apertures cut in the sides of the reflector, and are easily adjusted to the proper distance from the ball.

Wherever the light is required to be diffused equally round, the renewal of the lime may be effected still more easily, by using a cylinder, as represented in fig. 5, instead of a ball, which, being gradually raised while revolving, brings fresh portions in succession opposite the jets. In a reflector a cylinder occasions partial shadows at the top and bottom; still, however, the simplicity and certainty with which it may be renewed will probably entitle it to a preference even in this case.

These different instruments were prepared by Mr. Simms, of Fleet-street, to whom, for various ingenious suggestions, for the trouble which he has bestowed upon them, and the assistance which he contributed during the progress of the experiments, Lieutenant Drummond expresses himself greatly indebted.

The apparatus for supplying the lamps with gas is represented in fig. 6. It consists of two strong cylinders *A*, three feet high, the one for oxygen, the other for hydrogen: the gas is compressed two or three times in each, the latter by being generated under pressure, the former by being pumped in. To each of these gas-holders a governor, *B*, is attached, of one of which a section is shown; by which means, whatever be the variation of pressure in the gas-holder, provided it exceed that of the governor, the gas will issue at *x* with a uniform and constant stream; in the present instance under a pressure of 30 inches of water. Although this apparatus was of great use in the experiments at the Trinity House, and subsequently at Purfleet, by enabling the experimenters to keep within a small compass a supply of gas sufficient for two hours' consumption, and even to renew it without impeding the progress of the experiments, yet it may be remarked, that on a large scale the gasometers required would be much more simple, since compression would no longer be required. This apparatus was made by Mr. Samuel Crosley, the ingenious inventor of the gas governor.

"Our first experiments were on the illuminating powers of the different lights independently of the lenses or reflectors with which they are generally used. The method of shadows and that of equally illuminated surfaces, both depending on the same principle, but requiring different instruments, were employed, the former after the manner of, and with all the precautions recommended by Count Rumford; the latter according to the arrangements proposed by Dr. Ritchie, who was kind enough on this occasion to make several experiments with his own instruments, and without being made acquainted with the results previously obtained by us. The standard we used was an excellent Argand lamp

Mechanical
Processes.

Compara-
tive experi-
ments.

Manufactures.

$\frac{7}{8}$ inch in diameter, supplied with the finest spermaceti oil, and capable of supporting a flame $1\frac{1}{4}$ inch in height. The following results were obtained.

		Stand- ard.	Wax candle $1\frac{1}{2}$ in diam- eter, the wick consisting of 40 threads.
Mean of	5 observations by shadows...	1	= 9.1
French lamp	9 ditto	8.7	
	6 ditto by illuminated surfaces	12.1	10.4 = 94.6
Oil gas burner same diam. as standard	4 ditto by shadows.....	0.95	= 8.7
Lime-ball or cylinder $\frac{3}{4}$ inch dia- meter	2 ditto	9.2	
	2 ditto	10.4	
	4 ditto by illuminated surfaces	18.6	13.5 = 122.9
	10 ditto	16.9	

"The light of the ball depending upon the intensity of the heat is very different at different parts, being greatest opposite the jets, and diminishing towards the sides. The mean of the greatest and least intensity is taken in the above Table: and, moreover, though the greater number of observations might appear to warrant giving greater weight to their results, yet being made on the same day, and under the same circumstances, it was found that the results seldom differed, whatever might be the number of observations; hence the arithmetical mean is taken, and we obtain this remarkable result, that the light emitted by a lime-ball only $\frac{3}{8}$ of an inch in diameter, heated by two jets, is equal to 13 Argand lamps.

"With respect to the intensity or intrinsic brightness of the different lights, the property on which their utility in Lighthouses more immediately depends, we have the following results:

"The intensity of

	Mean.	
French lamp, mean 11 observations by shadows = 4.1		
French lamp, mean 8 ditto = 3.8	4.0	times in
Oil gas 6 ditto = 0.85		the inten-
Lime 6 ditto = 263.9		sity of the
Ditto 3 by illuminated surfaces.. = 264.4	264.1	standard.

"These results were obtained by screening the different lights, and then placing equal apertures opposite each, changing the apertures and taking the mean to destroy the effect of any inaccuracy in size. The intensity of the lime-ball being therefore 264 times that of the Argand lamp, a single reflector illuminated by the former will be equal to 264 reflectors illuminated by the latter; but the divergence of the reflected light, depending upon the size of the luminous body in the focus, will be smaller with the ball than with the lamp in the proportion of about 3 to 8: hence in such a Lighthouse as that of Beachy Head, 8 reflectors may be substituted for 30, and yet an effect would be produced 26 times greater than that of the present light, the most perfect of its kind in this Country.

"By similar experiments it was found that the French lens was equal to 9.1 reflectors; and if the effect of the additional lenses and reflectors which ought to accompany it, and which has been estimated at one-seventh, be added, then the lens is equal to 10.4 reflectors. In like manner, therefore, the effect of a single reflector with a lime-ball would be equal to 25 times that of such combination of lenses.

"Such appear to be the singular and important results of our late experiments at the Trinity House. Made as they have been with every precaution, by different individuals, with different instruments, and unbiassed by the knowledge of each other's results, I see no reason to

doubt their accuracy; and the comparative appearances of these lights, when exhibited at a distance of ten miles, to which I shall presently allude, though not admitting of being reduced to numbers, confirm the striking superiority of this method of illumination.

"It may now perhaps be asked, at what expense can such a light be maintained? can the gases by which the requisite heat is produced be procured at such a price as to compete with oil or coal gas? The data I possess for forming an estimate of the expense of the gases are very scanty, but the quantity consumed was accurately determined; at the same time the consumption of the other lights was also tried, and the results are as follows:

	Consumption in $3\frac{1}{4}$ hours.	Expense per hour.
An Argand lamp seven-eighths of an inch in diameter	1 gill	0.69 penny
The same placed in a reflector. .	$1\frac{1}{2}$ gill.	0.83 penny
The French lamp	2 qts. $\frac{1}{2}$ pt. 1s. $2\frac{1}{2}$ d.	

"The lime required 4 cubic feet of hydrogen, and 2 of oxygen per hour, and the probable expense is 5d. per hour.

"In a revolving light of the first class, containing 30 reflectors, the expense per hour would therefore be about 2s. 1d. If the French method were employed, the increase of light would be $\frac{1}{10}$ th, and the expense only 1s. $2\frac{1}{2}$ d. per hour. If six reflectors illuminated with lime-balls were used, which would probably be sufficient, the probable expense would be 2s. 6d. per hour, and the increase of light 26 times.

"If this estimate be erroneous, I think it will prove to be so in excess; admitting, however, that the expense should in the first instance somewhat exceed what has been stated, it may in this as in every similar instance be expected, that after a little experience, considerable reduction would be effected. This is a new source of artificial light, differing from every other at present in use, and the materials by which it is produced are among the most abundant products of nature; but, never having yet been applied on a great scale to any practical purpose, it has not hitherto been an object to obtain them in a separate state at a small expense. When this is effected, it will no doubt receive many useful and important practical applications.

"Meanwhile, however, the case in question may perhaps be regarded as one in which expense ought not to be a primary object of consideration. On all ordinary occasions, the preference of one mode of illumination to another is a question of convenience, luxury, or economy; but in this it assumes a more important character, for it involves to a great extent the preservation of life and property."

To complete the preceding account, it only remains to add a description of the appearances presented by the different lights when exhibited at a distance; and, to those who have entered with any degree of interest into the above details, such a description, it is hoped, cannot fail of proving acceptable.

The experiments at the Trinity House being concluded, the whole of the apparatus was removed to Purfleet, where on a knoll of chalk about 100 feet above the river a temporary Lighthouse had been erected, and, being fitted with the requisite Machinery, the different lights were made to revolve in succession, and the appearance which they presented, as well as the duration of the light, were observed from the Trinity House at Blackwall, a distance in a straight line of $10\frac{1}{4}$ miles

Mechanical
Processes.Expense
of the
light.Experi-
ments con-
tinued.

Manufac-
tures.

The four faces of the revolving Machine were thus occupied:

No. 1. A single reflector 21 inches diameter, 3 inches focal distance, with an Argand lamp.

No. 2. Seven reflectors with ditto.

No. 3. French lens, with its lamp.

No. 4. Single reflector with lime-ball.

The respective lights were accurately placed in focus. On the evening of the 10th of May, the Machine performed one revolution in eight minutes. Captain Pelly of the Trinity House made the following observations on the different lights from the Trinity House wharf, Blackwall, 10½ miles distant.

No.	Duration.		Divergence.	Computed maximum Divergence.
	min.	sec.		
1	0	25	17.40	17.81
2	0	25	17.40	17.81
3	0	7	5.17	5.18
4	0	9	6.12	6.7

When No. 4, the reflector lighted with the lime-ball, was turned towards the wharf, the light was so great that the shadow of the hand and fingers was distinctly visible even on a dark brick wall, while no such effect was discernible when the other lights were turned in the same direction.

In order more justly to estimate their comparative effects, No. 4 was removed to a temporary tent about twenty-five yards to the right of the Lighthouse, as far as the edge of the cliff would permit, and, on the evening of the 25th and 31st of May, regular series of experiments were made. The inventor being engaged at Purfleet, directing these exhibitions, had not an opportunity of witnessing their effects at Blackwall; but Captain Basil Hall, R. N., who, from the interest which he took in these experiments, was an attentive observer of all that occurred, kindly favoured him with the following interesting account:

"4, St. James's Place, 1st June, 1830.

"MY DEAR SIR,

Letter from
Captain
Basil Hall
to Lieute-
nant Drum-
mond.

(844.) "You wished me to take particular notice of last night's experiments with the different kinds of lights exhibited at Purfleet, and observed at the Trinity House wharf, Blackwall; but I have little to add to what I told you respecting those on the evening of the 25th instant; indeed it is not within the compass of language to describe accurately the details of such experiments, for it is by ocular evidence alone that their merits can be understood.

"Essentially, the experiments of last evening were the same as those of the 25th, and their effects likewise. The degrees of darkness in the evening, however, were so different, that some particular results were not the same. The moon last night, being nine or ten days old, lighted up the clouds so much, that, even when the moon herself was hid, there was light enough to overpower any shed upon the spot where we stood by your distant illumination; whereas on the 25th, when the night was much darker, the light cast from the temporary Light-

house at Purfleet, in which your apparatus was fixed, was so great that a distinct shadow was thrown upon the wall by any object interposed. Not the slightest trace of any shadow, however, could be perceived when your light was extinguished, and any of the other lights were exposed in its place.

"In like manner, on the evening of the 25th, it was remarked by all the party at the Trinity wharf, that, in whatever direction your light was turned, an immense coma, or tail of rays, similar to that produced by a beam of sun-light in a dusty room, but extending several miles in length, was seen to stream off from the spot where we knew the light to be placed, although, owing to the reflector being turned too much on one side, the light itself was not visible.

"Now, last night, there was none of this singular appearance visible; but whether this was caused by the presence of moon-light, or by the absence of the haze and drizzling rain which fell during the evening of the 25th, I cannot say. I had hoped that the appearance alluded to was to prove a constant accompaniment to your light, in which case it might, perhaps, have been turned to account for the purposes of Lighthouses. If in hazy or foggy weather this curious effect of reflected light from the atmosphere be constant, it may help to point out the position of Lighthouses, even when the distance of the observer is so great that the curvature of the Earth shall render it impossible for him to see the light itself.

"The following experiments tried last night were the same as those of the 25th, and certainly no comparative trials could be more fairly arranged.

"*Experiment 1.*—The first light exposed was the single Argand burner with a reflector. This was quite distinctly seen, and all the party admitted it to be a good light; after several minutes this was put out.

"*Experiment 2.*—The seven Argand burners were next shown, each in its reflector; and this was manifestly superior to the first, but how much so I cannot say, perhaps four times as conspicuous. Both these lights had an obvious tinge of brown or orange.

"*Experiment 3.*—The third light which was exposed (on the seven Argands being put out) was that behind the French lens; and I think it was generally admitted by the party present, that this light was whiter and more intense than that from the seven Argands, though the size appeared very much the same.

"*Experiment 4.*—The fourth light was that which you have devised, and which, instead of the clumsy word 'lime,' ought to bear the name of its discoverer. The Drummond light, then, the instant it was uncovered, elicited a shout of admiration from the whole party, as being something much more brilliant than we had looked for. The light was not only more vivid and conspicuous, but was peculiarly remarkable from its exquisite whiteness. Indeed there seems no great presumption in comparing its splendour to that of the sun; for I am not sure that the eye would be able to look at a disc of such light, if its diameter were made to subtend half a degree.

"The next series of experiments was the most interesting and decisive of all. Each of the lights above enumerated, viz. the single Argand burner, the seven Argands, and the French lens, were exposed, one at a time, in company with your light, in order to try their relative brilliancy.

"*First comparative experiment.*—The single Argand

Mechanical
Processes.

Manufac-
tures.

burner was first exposed to this comparative ordeal, and nothing could be more pitiable than the figure it cut; many of the party could not see the Argand light at all, while others could just detect it 'away in a corner,' as some one described it. It was also of a dusky orange tinge, while your light was of the most intense whiteness.

"*Second comparative experiment.*—The seven Argand burners were now substituted in place of the single light. All the party could now see both lights, but the superiority was not less obvious; I really cannot affix a proportion either as to size or brilliancy, but I should not hesitate to say that your light was at least six or eight times as conspicuous, while in brilliancy, or purity, or intensity of light, (for I know not precisely what word to use to describe the extreme whiteness,) the superiority was even more remarkable. All this which I have been describing was expressed, and appeared to be quite as strongly felt by the rest of the company, to the number, I should suppose, of five and twenty or thirty persons, who were all closely on the watch.

"*Third comparative experiment.*—The next comparative trial was between the French lens and your light. The superiority here was equally undeniable, though the difference in the degree of whiteness was not so remarkable; the French light, however, is so nearly similar to that from the seven Argands, that the comparison of each of them with your light gave nearly the same results, and all equally satisfactory on the score of your discovery.

"*Final experiment.*—The flashes with which the experiment concluded were very striking, and might I think be turned to great account in rendering Lighthouses distinct from one another. The revolutions were not effective, and, as I said before, there was no appearance last night of those enormous comets' tails, which swept the horizon on the night of the 25th, to the wonder of all who beheld them: neither could there be detected the slightest trace of any shadow from the light thrown towards us, and I suspect none will ever be seen, when the moon, whether the night be clouded or not, is of so great a magnitude.

"Such is the best account I can give of what we witnessed; and I need only add that there seemed to be amongst the company but one opinion of the immense superiority of your light over all the others brought into comparison with it.

"I am, &c.

"BASIL HALL."

"The advantage of such a light being fully recognised, attention may now be exclusively directed to remove some of those minor obstacles that might render its use in Lighthouses objectionable; and I have great pleasure in adding that the Trinity Corporation are desirous that every facility in their power should be afforded with a view to effect this object, and that a series of preliminary experiments is accordingly to be carried on at their expense."—*Philosophical Transactions* for 1830.

The results of these experiments, if they have been made, have not at present been published.

Lighting, Warming, and Ventilating Manufactories.

(845.) *Lighting of manufactories.*—This was formerly effected by means of candles or oil lamps; but, since the invention of gas-lights, which were at first wholly

employed for this purpose, most establishments and public buildings have been lighted by coal or oil gas, and it would not, therefore, have been necessary to have had a distinct Section on this subject, but for the sake of describing a new process, lately invented by Mr. Beale, whereby a most powerful illumination is produced from the refuse tar of a gas-house, and, therefore, at a very cheap rate, the expense for one light, equal to $4\frac{1}{2}$ Argand lamps, or to 35 wax candles of nearly an inch in diameter, being but three farthings for eight hours.

The only Works thus lighted at present, we believe, are those of Messrs. Enderby, at East Greenwich, where several processes are carried on, as rope-making, canvass weaving, the reduction of India rubber, &c., and where 35 of these lights are employed, one being at the entrance gate of the rope-walk, at a distance of more than two furlongs from the principal building. We have been favoured with an examination of this illuminating process, which is exceedingly simple and interesting, as will be seen from the following description:

A B C D E F (plate lvi. fig. 9) is an external tin or copper case, having a bottom F C, and below this bottom the space F C B E with a cock at E, the purpose of which will be explained as we proceed: *a b c d* is an internal tin or copper cylinder to contain the fluid tar; H is a handle by which it may be drawn out of the external case to be filled with the fluid at the valve *h*. This valve, of course, closes when the cylinder is withdrawn, by its own weight, and when the vessel is filled the valve is shut by pulling the wire seen passing through it; but when it is placed inverted in the outer case the pressure of the wire against the bottom F C opens the valve, and the fluid distributes itself at the bottom, fills the pipe *p p*, and ascends in the lamp tube to *k l*, the level of the aperture in the valve of the cylinder *a b c d*, where it is sustained by the pressure of the atmosphere on the principle of the bird fountain or the common Argand burner. In this state, if a light be applied to its surface *k l*, a slight lambent flame will be obtained, but scarcely perceptible; *m n* is a small pipe, about one-tenth of an inch in diameter, which is connected at *n* with a pipe passing to an air vessel, in which air is contained under a pressure of $1\frac{1}{2}$ pound per square inch, the compression being produced by a pump attached to a steam-engine or in any other way, and there is a stop-cock at *n*, whereby the pipe may be opened or shut at pleasure. K L is a broad open rim, which encompasses the lamp *k l*, and is adjustable upon it, and M N O P is a brass dome resting on this rim, open at top at O N, having an interior conical part attached, which reaches nearly to the upper edge *k l* of the lamp. This dome, placed as shown in the figure, and the stop-cock at *n* opened and properly adjusted for aperture, the lambent flame, before scarcely visible, is now seen rushing out at the aperture O N in a strong vivid white light, equal, as we have before stated, according to very accurate measurement by Dr. Faraday, to $4\frac{1}{2}$ Argand burners, and, by varying the size of the aperture N O, it may be made equal to 10 or more such burners. The pipe *v v* is to prevent the fluid rising above its level, and any fluid which may thus pass this way is let off at the cock E.

Such is the form of this exceedingly ingenious apparatus, which is at present, in all probability, very far from having attained all the perfection of which it is susceptible, although in its present form it answers its purpose admirably in the Works where it is employed.

Mechanical

minating
process.
Pl. lvi.
Fig. 9.Lighting
manufac-
tories

Manufac-
tures.
Application
of this light
to Light-
houses.

In the preceding Section we have entered at some length into a description of Drummond's light, which is, of course, very much superior to it in its intensity, and, if the latter could be rendered as simple as the circumstances of a Lighthouse require, it would be hopeless to expect any thing which could, by possibility, compete with it: but if, after sufficient experiment, it should unfortunately be found irreducible to the requisite degree of simplicity, there is, perhaps, nothing that presents a greater hope of improving the present system of lighting our Lighthouses than the apparatus we have just described, which, at a great reduction of expense, would increase the present illuminating power tenfold.

The theory of its extraordinary illuminating effect is to us somewhat mysterious, but the fact is undeniable. The pipe which admits the stream of air is, as we have said, but one-tenth of an inch in diameter, but it may be closed to any small quantity less than one-tenth, and, by trial with the cock, the adjustment is made which produces the best effect, which is considerably less than the whole, so that the quantity of air requisite to supply twenty or thirty of such lamps is very inconsiderable. At Messrs. Enderby's the pumping is effected by a small power borrowed from the steam-engine, but in a Lighthouse, if this means was thought inconvenient, various other mechanical means might be had recourse to to keep up the pressure required.

Warming
manufac-
tories.

(846.) *Warming manufactories.*—In the preceding two Sections, and in a subsequent one, we have shown the manner in which a gas, in the one case, and a fluid in the other, is conducted from one general reservoir to be delivered at certain places where its use is required. Heat, which is nearly as essential in some cases as light or water, is in a manner somewhat similar sent from one general focus to be distributed throughout very large buildings or manufactories; and we therefore shall, in connection with the Gas Works and Water Works, treat of the means which have been proposed for warming and ventilating buildings. There is, however, one great line of distinction between this and the above two cases, for in these the gas or water is conducted along pipes impervious to either, whereas heat is unconfined, and radiates and escapes in every foot of its progress; it is necessary, therefore, that the source should be as near as possible to the place of delivery; whereas in the two former cases the distance is no otherwise of consequence except as regards economy.

Any person who has visited our cotton, silk, and flax manufactories in Yorkshire, Lancashire, and in Scotland, would be instantly struck with the impossibility of warming buildings and apartments so extensive with common fire-places, at least, without a great risk of danger from fire, and without great inequality in temperature between those places in the immediate vicinity of the fire and others distant from it; but by the means which we are about to describe, every part is brought to an equal and steady temperature, equally conducive to the health and comfort of the hundreds of children and others employed, and to the perfect execution of the work to be performed. In a spinning establishment the principal occupation of the children is the uniting together the ends of fine cotton, silk, or flax, which break during the process, and it would be impossible for the fingers to feel with sufficient delicacy if the temperature were not preserved at a sufficient height to prevent any sensation of cold, not to mention that, besides this, the material itself works best at a certain temperature.

In proportioning and arranging such an apparatus as is here referred to, however, there is one essential point to be previously considered, *i. e.* ventilation. We may readily, by confining the air within any building, warm that air up to a given temperature, but in this state, after a short time, it would become unwholesome and unfit for respiration.

Mechanical
Processes.

(847.) It appears, from accurate experiment, that a man consumes about 32 cubic inches of oxygen in a minute, which is replaced by an equal bulk of carbonic acid gas from the lungs. Now, the quantity of oxygen in atmospheric air is about one-fifth, hence it follows that the quantity of atmospheric air rendered unfit for supporting either combustion or animal life by one man in one minute, by respiration only, amounts to 160 cubic inches. But a man makes twenty respirations in a minute, and draws in and expels forty inches each time, consequently the total quantity contaminated by passing through the lungs in one minute amounts to 800 inches, or nearly three gallons. But during the same time a man discharges a considerable quantity of vapour from the lungs. Experiments on this subject give results which differ considerably, but it may be taken at six grains per minute at the highest, this quantity being sufficient to saturate 800 inches of air with vapour at the temperature given out in respiration; and it is this vapour mixing with the carbonic acid gas which renders the expelled air lighter than the common air, and by which it rises immediately it is discharged from the lungs, and thereby avoids being again inspired—one of those admirable arrangements of an all-wise and all-powerful Creator, of which we have so many instances, and to which every new philosophical fact that is discovered is adding new examples. Other sources of deterioration of the air of a room may be enumerated; *i. e.* insensible perspiration, the consumption of oxygen by candles, lamps, and other lights, &c., which, taken together, show the absolute necessity of some means of ventilation wherever a number of persons are congregated, and more particularly where artificial warmth is superadded to the natural temperature of such a room or building. And as we have seen that the vapour with the azote, both lighter than common atmospheric air, by their admixture with the carbonic acid gas, although the latter is of itself heavier, become, upon the whole, specifically lighter, the contaminated air will ascend to the top of the building, and, therefore, this is naturally the situation in which the valve or other contrivance should be placed for ventilation.

Ventilation.

When the processes carried on and the number of persons employed are constant, a permanent means of ventilation may be adopted, but if these are variable, the aperture through which the contaminated air escapes should be so arranged that it may be suited to the necessity of the case, by admitting of opening and shutting, or of being partially opened or shut as the case may require.

The apparatus for heating should also be so adjusted that it may always supply such a quantity of heat as is carried off by the hot contaminated air, or the difference of heat between it and that of an equal bulk of common air at the temperature of the atmosphere.

Different means have been recommended and adopted for the warming of buildings: one by steam pipes passing along the rooms; a second, by air heated in pipes and discharged into the building; and a third, by the circulation of hot water through iron pipes, a circulation which is kept up by the hot water having a tendency to

Different
means of
warming.

Manufac-
tures.

ascend by being rendered lighter by expansion, and, after cooling, becoming specifically heavier, so that after circulation the water which has been cooled in the process enters at the bottom of the boiler to be again heated, when it ascends to the top, passes through the pipes, enters again at the bottom, and so continually. We might also mention a mode of drying formerly had recourse to, which was simply effected by an iron stove containing the fire, and pipes for conducting away the smoke and flame which were thus heated, and thus conveyed a close unhealthy degree of heat to the room in which they were placed.

Warming
by steam.
Pl. liv.
Fig. 1.

(848.) *Warming by steam.*—Fig. 1. plate liv. is a section of a silk manufactory, belonging to Messrs. Shute and Co., of London, situated at Watford, Herts, and is described by the late ingenious Mr. Tredgold, in his *Treatise on the Warming and Ventilating Buildings*. The manufactory was formerly heated by thirteen iron stoves, with pipes for the smoke passing out of the windows and through the roof; but, in 1817, the proprietors had the stoves removed, and a steam apparatus put up by Messrs. Bailey, of Holborn, which has been in constant use ever since. The arrangement is very simple. B is the boiler and furnace house outside the building, the smoke being conveyed away through the funnels and chimney G, seen in fig. 1. A is the main steam pipe up which the steam ascends from the upper part of the boiler. Into this first pipe are inserted the longitudinal pipes suspended near the ceiling of each room, marked S S S S; each of these pipes has a valve to regulate the supply of steam, and a siphon at the other extreme, the construction and purpose of which will be described below. C is a small pipe for returning the water of condensation to the boiler from the upper three floors, that collected from the steam pipe of the lower floor being used for washing and other purposes. In order to accumulate the water of condensation the longitudinal pipes, it will be seen, are placed at a slight degree of inclination down towards the pipe C, so that as the water is formed in these pipes, it runs gently down towards the further end, there enters the descending small water pipe C, whence it passes again to the bottom of the boiler, retaining still considerable heat. Mr. Tredgold observes, that the power of making a good arrangement in this case was extremely limited, the mill being already full of Machinery, but the advantages of it are still great, which he thus enumerates: 1. A considerable reduction in the rate of insurance. 2. The absence of all smoke, dust, and ashes, which had been found very injurious to the silk in the former way of warming. 3. A saving of fuel, and of time and labour in attending to the fires. 4. An equable heat instead of the partial one of the stoves, and a regular supply of fresh air into the mill warmed by the main pipe A. 5. The labour proceeds without interruption and in a comfortable temperature. 6. The children are free from chaps and chilblains in the winter season owing to their having warm distilled water for washing. The mill is 106 feet 4 inches by 33 feet; the upper story is 8 feet high, is warmed by a pipe of 3 inches diameter; the next story, 8 feet 8 inches high, is warmed by a pipe of 4 inches; the next, 9 feet high, by a pipe also 4 inches; the next or lower story, 9 feet high, by a pipe of 5 inches diameter. The building is supplied with water from a cistern at W.

Self-acting
siphon.

It remains for us to explain the nature and uses of the siphon above referred to, and not shown in the

figure; this will appear in the course of the following general observations. In every part of the distributing apparatus it is necessary to prevent any considerable quantity of water collecting, for when steam is admitted into the pipes, &c. and meets with a great surface of cold water remaining in them, it condenses the steam so rapidly as to endanger the boiler and pipes, should they not be firm enough to resist the sudden external pressure thus brought upon them. When it is possible to have the boiler at a lower level than the pipes and other steam vessels, it is best to return the water of the condensed steam into the boiler again, because it not only saves fuel, but also requires only a small supply of fresh water, which is an object of some importance in certain situations. It is, however, desirable in some cases to allow the water of condensation to collect in the pipes, and to continue to give out heat after the steam has ceased to flow into the pipes. Stop-cocks may in these cases be employed, and which afterwards allow the water to be educted from the pipes: the same cocks also serve for letting the air out of the pipes when the steam is first admitted, but, when the water is returned into the boiler, the advantage of this supply of heat cannot be reserved; and in these cases a self-acting apparatus is commonly employed for taking off the water of condensation, one kind of which is the siphon above referred to. This is represented in plate liv., fig. 2. The pipes are so fixed that A is the lowest point of a longitudinal pipe; thus any quantity of water that may be formed in the pipe will flow into the siphon A B C at A, and run to waste, or otherwise, at C, the water in the legs of the siphon acting as a trap to the steam in the pipe A. The length of the leg A B of the siphon should not be less than is equivalent to the force of the steam in the pipes, and must, therefore, be determined accordingly. For example, when the steam is worked at the rate of 10 pounds per square inch, the column of water should not be less than ten feet, and even with this pressure there will be considerable oscillations unless a valve be placed somewhere intermediate, as at D. When the legs are both filled with water, and at rest, this valve should be open so as to close whenever the water has a tendency to return into the pipe. The siphon should also be large enough to take away with ease all the water formed by condensation; at the same time it should not be too large, because there would then be a loss of heat in the leg A B, from its being filled with steam; and in all cases the siphon should be carefully protected against freezing. In connection with the siphon it is usual to place a cock for letting the air out of the pipe instead of the stop-cock above referred to; such a one is shown at E, and it is kept to range with the lower part of the pipe, because the air being heavier than steam it will occupy only the lower portion of it.

Mechanical
Processes.

But when it is not convenient to get depth for a siphon, a steam-trap or valve, to open by a float ball, is employed, and Mr. Tredgold thinks most conveniently, as follows: Let B C, fig. 3, be a square box attached to the end A of the steam-pipe, and D a hollow copper cylinder fixed to a conical valve E; then when steam is condensed the square box will fill with water, which will float the hollow cylinder, consequently the water will escape and run by the pipe F into the drain, at all times when the quantity of water in the box is greater than is required to just float the cylinder; and when there is less than will float it the

Fig. 2.

turesWarming
by hot
water.Mr. Price's
patent.Pl. liv.
Fig. 4, 5,
6, 7.

valve will be closed. In this case also a stop-cock S will be necessary to let out the air while the pipes are filling with steam.

(849.) *Warming by the circulation of hot water.*—This is a very ingenious process; it consists in having a boiler resembling the boiler of a steam-engine with two pipes, one inserted in the bottom of the vessel, and the other from a point near the top. These pipes, after passing in all required directions through the building, are united in one, and the whole filled with water; the heat of the fire being now applied, the cold water at the bottom being heated will ascend to the upper part of the boiler, and hence continue to ascend in the rising pipe, but communicating its heat to the air as it proceeds it will pass down the descending pipe, where it re-enters the bottom of the boiler to be again heated, when it ascends as before, and thus a continual circulation is kept up and heat distributed to almost any extent. At the Lunatic Asylum for the County of Middlesex, the ingenious Architect, Mr. Sibley, under whose direction that building was erected, has heated the whole establishment by this means from four boilers, each of which gives circulation through half a mile of pipe.

Commonly the heat thus communicated is by radiation from the pipes containing the water in circulation; but Mr. Price, of Bristol, has lately taken out a patent by which the air is first heated by its contiguity with the hot water pipes and cylinders, and is afterwards distributed through the building. An account of this patent is given in the 56th volume of the *Repertory of Arts*. The improvement proposed to be effected consists in a certain arrangement and combination of pipes and vessels connected with the upper part of the ascending pipes from the boiler, which ascending pipes contain the column of heated water, in order to receive the increase which takes place in the volume of water contained in the apparatus as it becomes heated, and also in making the cylindrical pipes to pass one within the other, agreeably to the following description given in the specification. Fig. 4, plate liv., is an elevation of the apparatus, figs. 5, 6, 7 are horizontal sections of what the patentee calls his water-stove, being a series of vessels one within the other, by which the heat is communicated from the hot water to the air; fig. 5 is a vertical section of the same vessel, which will be understood from the following description, the letters of reference being the same in all the figures. A represents the boiler, which is of the kind commonly used in steam-engines, the only difference is in the quantity of water, it being in this case quite filled; the furnace is also nearly the same but need not be so large, and the fuel is applied exactly in the same way. B is an ascending pipe joined to the upper part of the boiler to convey the hot water to the cylindrical vessel C, and D E F G H I, which are peculiar to this patent, form what is called the safety reservoir. The vessel C is of such dimensions as will facilitate the union of these pipes with it, while it serves for the purposes of the reservoir above mentioned, and may contain any quantity of water beyond what is absolutely necessary for the performance of the apparatus, thereby allowing hot water to be drawn off for any useful purpose without interrupting the heating operation. D is a pipe joined to the top of the vessel C, and to the bottom of the vessel E, in order to convey any increased and superfluous quantity of water from C to E. The pipe D is curved down

and up again to form an inverted siphon, which prevents the circulation of the water which might otherwise take place between C and E. E is in the form of a frustum of a cone, open at top, and the pipe D joins to it at the bottom. It receives the water that may proceed from C in consequence of expansion, as above stated, and should be about $\frac{1}{20}$ in bulk of all the water contained in the other part of the apparatus, this being the amount of expansion in water between the temperatures of 52° and 212°. The object of the conical form of this vessel is, that the extent of surface it exposes to the atmosphere may be diminished and the evaporation proportionally lessened as the water rises within it. F is a cylindrical vessel within which the former is placed to receive such water as may overflow. The waste of water from the apparatus, by evaporation or otherwise, may be supplied by other water introduced into this vessel F. G is a pipe descending from F to C, with a stop-cock in it at H, to let down the water from F to C. I is a short pipe joined to the lower part of the loop in the pipe D, and to the pipe G, where it joins to the top of the vessel C, and has a stop-cock at K. When this is opened it allows the loop of D to empty itself of water, which might otherwise obstruct the escape of the air from the apparatus when it is to be filled for working. L is a pipe from the bottom of the vessel C to the bottom of the stove M. N is a pipe descending from the bottom of the stove M to the bottom of the boiler A, and serves to conduct the water from M to A to be reheated. The vessel C should never be entirely empty, and to ascertain the height of the water within it a small vessel s is joined at the lowest part by the pipe r and cock t, so that when the cock t is opened, the cocks H or K being also open to establish a free communication with the atmosphere, the water will rise within the vessel s to the same height it stands within at C. The vessel s is open at top, and is on a higher level than the top of C, and if made of glass the height may be immediately seen.

It remains to describe the stove M, which is formed of concentric cylinders placed one within the other, leaving narrow spaces between them, which are united in pairs at top and bottom, so that the space left between each pair will serve as a vessel to contain water, as represented by the dark parts in fig. 5 and 7. The spaces ff, between the several cylinders, c, d, e, are left vacant for the passage of the air which is to be warmed by its passing through the stove. The bottom of the stove is raised up from the floor of the apartment in which it is placed in order to admit the external air to pass freely, and which thereby gets heated in its passage. The top of the stove is a dome a, covering all the cylindrical vessels of which the stove is composed, and receiving all the air which rises through the open spaces; at the top of the dome is a turning register, of the same kind as is usually applied in other air-stoves, whereby the quantity of hot air admitted is regulated in the usual way. h is a small tube joined to the highest part of the top branch xx, which connects the three vessels c, d, e; this tube passes up through the centre of the turning knob of the register, at the top of the dome a, and has a small cock m at the top, which is opened to allow the air to escape from the open spaces, when the tubes are first filled with water, but when they are full this cock is shut.

To fill the apparatus for action all the stop-cocks, H, K, t, and m, must be opened, then, water being intro-

Processes.Method of
filling the
apparatus.

Manufactures.

duced into the vessel F, it will flow through the pipe G and cock H into the vessel C, and thence, by the pipes B, L, N, into the boiler A, and the stove M, till every part is completely filled. When the water begins to issue at *m* that cock must be shut; and when the height of the water in the glass tube *s* indicates that the vessel C is full all the other cocks must be likewise closed. It may be observed, however, that although we here suppose the apparatus to be filled from the vessel *d*, this is by no means essential; it may be introduced either by a pump or pipe into any part of the apparatus, even into the boiler A, the only condition being that every part be completely filled up to the level of the vessel C. The fire is then lighted beneath the boiler A, and as the water within it becomes heated, and consequently becomes specifically lighter than the water in the other parts which have not been heated, the circulation will begin, the colder and heavier water in the descending pipe overbalancing the hotter and lighter water in the ascending pipe, and therefore the cold water will force its way into the lower part of the boiler, and displace and force from it a corresponding quantity of hot water up the ascending pipe B, into the vessel C; it is obvious, also, that a corresponding quantity of water will run down the descending pipe L, and pass through the stove M, where it will communicate its heat as already described. By this means the water, being cooled and consequently heavier, will descend through the pipe N into the bottom of the boiler, and thus the circulation will be continued as long as the fire is kept up. It is recommended that the ascending pipe and vessel C be covered with wrappers of non-conducting substances, to avoid the loss of heat by radiation and contact with the air, that the ascending column of water may be kept hot while that in the descending pipe is cool.

Warming by hot air.—The method of warming by hot air is considered to be in some cases more economical, but not so generally applicable as the methods above described. When it is practised, a stove or furnace is heated, and the air from without the building is made to pass under the same and enter a space which surrounds the furnace; by this means it is heated in its passage, and, at some point or at various points above the furnace, it is thrown into the room or rooms intended to be warmed, frequently very near the upper ceiling. The stratum of hot air thus found in the upper parts of the building communicates its heat to the next lower stratum till the whole is of proper temperature, and, when the house or manufactory thus heated consists of several floors, openings are made between the upper and lower rooms, the latter deriving their heat from the hot air descending from above. In general, however, this method of warming requires more care in keeping the large doors and openings of the buildings closed than is consistent with a manufactory; but it has been applied with great advantage to theatres, churches, and hospitals. It is attended with great convenience in ventilating in hot weather, for then the same apertures, which form the passage for the air made hot by passing the stove in the Winter, serve to admit the external cold air, whereby a more equable temperature is kept up throughout the year than is attainable by the other methods above described, unless supplied with other means of ventilation.

Public Sewers.

(850.) It may perhaps be questionable whether the
VOL. VII.

Public
sewers.

consideration of sewers is appropriately introduced into this Treatise, but when we consider the immensity of the work, the many miles of open and covered sewers which are employed to drain the vast Metropolis of England, a sort of city beneath a city, and their importance in contributing towards the cleanliness and health of a million and a half of human beings, we think some notice of them is required while we are treating of Works of public and domestic convenience.

It appears that the first Acts of Parliament relating to public sewers were passed in the reign of Henry VIII., and are still in force, although wholly inconsistent with the present state of the Metropolis, at the same time that they interfere with the rates, &c., relating to all the sewers which have been since, or that shall be in future, added. These circumstances have led to various complaints, and, in consequence of petitions presented to Parliament, a Committee was appointed by the House to examine into and report upon the present state of the sewers, and the laws and commissions connected with them, from which Report and examinations, which fill a thick folio volume, the following particulars have been extracted.

“The Metropolis, and the adjacent districts within a circle of 10 miles of the Post Office, are divided into seven Trusts or Boards of Commissions, for the purpose of maintaining the several sewers, water-courses, &c., within their respective districts, each having a separate and independent jurisdiction of its own. Five of these Commissions are administered under local Acts, but two of them take as their guide the old law of sewers, dated as far back as 23d Henry VIII.; which must obviously be altogether inadequate to the complicated wants of the present time. Equally inconsistent with modern notions is the want of publicity and responsibility which characterizes the system established by the old statute. These defects, coupled with the want of uniformity in the administration of the law, and the want of uniformity in the operation of the Commissioners of the different Boards acting independently of each other, call loudly for a remedy, for there can be no question that, however well the system as a whole may operate towards the main object of drainage, it will admit of great improvement, and the charges are certainly very unequally and disproportionally levied. It appears from the examination that a person having property in Finsbury and in Westminster, or in the City and Tower Hamlets, will find himself under the operation of different and contrary rules, whereby he may be led from a knowledge of the regulations of one district to violate those of the other. This part of the sewerage of the Holborn and Finsbury district is conducted through the City into the Thames; and the sewers of the former districts having been greatly improved and enlarged, the quantity of water carried towards the river became so great as to render the sewers of the City inadequate to carry off their contents; which, in addition to the waters from the high lands, were at one time absolutely forced back into the houses from the quantity which occupied the main sewer, and thus after every fall of rain the houses in the vicinity of the City were regularly inundated. This has now been remedied by the Corporation at a great expense and with excessive labour; it proves, however, that combination and uniformity of action are highly requisite to the well-conducting of such a complicated system; and if no speculations have been carried on it is to be attributed to the honourable

Mechanical

politan
trusts.

Manufactures.

characters of the Commissioners, for the irresponsibility under which each acts furnishes great facilities for such transactions. The Committee in their Report express their satisfaction, that whatever may be the defect of the existing laws, they appear to have been administered with good faith and integrity on the part of the Commissioners."

Annual expenditure and receipt of the Westminster Trust.

The great extent and expenses attendant on these works may be seen from the following statement of the receipt and expenditure of the Westminster and City of London Divisions; it will be seen also how much beyond these is due to individual exertion.

The receipt and expenditure for the last ten years are exhibited in the following Table:—

Year.	Receipt.	Expenditure.
1824 . .	£29,981 16 11	£24,168 1 1
1825 . .	28,837 10 10	24,360 4 1
1826 . .	22,740 19 6	29,410 10 0
1827 . .	28,375 17 11	23,505 17 10
1828 . .	19,209 2 6	27,340 15 3
1829 . .	39,424 1 10	33,998 13 9
1830 . .	28,009 17 9	30,427 8 11
1831 . .	35,394 19 7	23,643 0 11
1832 . .	11,274 12 3	19,724 12 10
1833 . .	37,546 3 2	33,410 3 7
	£280,795 2 3	
Balance carried to the account of 1833 .	10,805 14 0	
	£280,795 2 3	

This large receipt and expenditure has reference to the following parishes, either wholly or in part under the jurisdiction of the Commissioners:—

St. Clement Danes	Wilsden (part)
St. Mary-le-Strand	St. Mary-le-bone
St. Paul, Covent Garden	St. Mary, Paddington
St. John Baptist, Savoy	St. George, Hanover-square
St. Martin-in-the-Fields	St. James, Westminster
St. Ann, Westminster	St. Margaret, ditto
St. Giles-in-the-Fields (part)	St. John the Evangelist, ditto
St. George, Bloomsbury (part)	St. Luke, Chelsea
St. Pancras (part)	St. Mary Abbot's, Kensington
St. John, Hampstead (part)	All Saints, Fulham (part).

There are other parishes named in the Commission, but not included in the local Act under which the Board administer. From a Return, given in evidence by Mr. William Fowler, it appears that the quantity of feet of open and covered sewers built at the cost of the Commission since 1807 is 9578, while, during the same period, the Public, at their private cost, and without any assistance from the sewers' rate, built 91,708 feet.

City of London Trust.

The Commissioners of the City and liberties of London division have within their jurisdiction about 17,600 houses, the rental of which, assessed to the sewer-rate, is £792,904. This comprehends, either wholly or in part, 113 parishes, of which the population is estimated at 122,316. The number of Commissioners is 107; seven constitute a quorum; and the average number who attend the Meetings is from twenty-five to thirty. The salaries of the officers only amount to £570 per annum; and, since the year 1756, about 114 new sewers have been built, wholly or in part. Very great improvements have taken place of late years in the management of this Trust; and the sewers are, generally speaking, in an unobjectionable state. Complaints have been made by several of the inhabitants, who have large and valuable properties in the most crowded parts of the City, of the want of drainage in their neighbourhoods—a deficiency which not only produces serious inconvenience, but has

been prejudicial to health. But there are obstacles of considerable magnitude in the way of the necessary improvements. To construct sewers of sufficient depth to drain the properties in question would endanger several buildings,—one or two of them ecclesiastical structures,—and produce considerable risk of loss and damage; and the Commissioners have hitherto, in consequence of their defective powers and misunderstanding with the individuals who complain, refrained from interfering.

The amount received and expended by the City of London division for the last ten years is as follows:—

Year.	Received.	Balance in hand, after defraying Expenses.
1824 . . .	£5,643 0 0	
1825 . . .	7,500 19 10	
1826 . . .	9,281 11 2	£77 13 10½
1827 . . .	12,430 7 5	701 18 5
1828 . . .	13,006 14 3	1199 13 3
1829 . . .	13,307 14 1	2787 18 7
1830 . . .	14,983 7 9	2822 13 7
1831 . . .	10,068 10 6	
1832 . . .	12,041 5 1	
1833 . . .	17,718 9 4	4379 1 11

The five other Trusts delivered in similar statements.

In the course of inquiry by the Committee several scientific men were examined, in order to ascertain what might be done towards removing nuisances proceeding from the sewage, and affecting the health of the Metropolis. Mr. Fuller, seconded by several medical men of eminence, proposed a plan for purifying the air, by erecting furnaces communicating at intervals with the main sewers; and also suggested the closing of the gully-holes, as they are termed, with traps, so as to prevent the escape of noxious effluvia; but as the expense of erecting these furnaces would be considerable, and as no successful experiment had been made which seemed to warrant the risk of the expense, the Committee decline pronouncing an opinion on the plan, especially as Dr. Faraday, though he approved of it as one likely to succeed, was cautious and guarded in expressing his opinion. The minor improvement of traps for diminishing the admission of foul air from the gully-holes has already attracted the attention of the Commissioners in several of the Trusts, and appears to have been applied with success.

The changes which are suggested by the Committee in the law of sewers are inconsiderable. They see so many objections to a Central Board superseding wholly or in part the Local Trusts—a change which they think would be unpalatable to the inhabitants of the respective districts—that they cannot recommend it without further consideration, and the intermediate trial of smaller improvements. They therefore recommend that, as the composition of the Trusts has given much and general dissatisfaction, (because, although consisting of respectable individuals, a great majority of them have neither the time nor the inclination to attend the Courts,) whenever a Commissioner has absented himself from a majority of the Meetings held for his district within the year, he shall be considered as having voluntarily resigned. It is also suggested that the number of Commissioners should be fixed; and that vacancies should be filled up, in the City of London, by the Common Council, as at present, and in the other Trusts by the vestries of the parishes in the respective districts, by rotation, and in proportion to their relative population

Mechanical Processes.

Recommendation of the Committee.

Manufac-
tures.

and rental. And in addition to this improvement (which would, of course, give the rate-payers a control over the Boards, and tend to destroy the close corporate system pursued) it is recommended that the interpretation of the law in the different Trusts should be uniform, instead of being, as at present, confused and contradictory; that the Courts should meet at fixed times, and be thrown open to the Public; and that the accounts should be subject to general inspection, publicly audited, and submitted annually to Parliament, copies being furnished to all rate-payers, on demand, at a reasonable price. They suggest that works of all kinds should be performed by public contract, with due notice given, but with the understanding that they are to be subjected to the approbation of the Commissioners; there being no public Works in which the inspection of responsible officers is so essential as in those connected with sewers, where defects, concealed easily, if not at once detected, are sure to be brought to light by entailing upon the district subsequently a load of vexation and expense.

The practicability of varying the amount of the rates according to the extent of the advantages enjoyed is attended with considerable difficulties. The principle on which a uniform rate was originally established has been already explained; and as long as the sewage was confined to the surface-drainage it was perfectly just. It certainly is now an unreasonable thing to impose precisely the same amount of rate on streets and houses which have no private underground drains, because there are no sewers within reach into which to conduct them, as upon other streets and houses amply provided with the accommodation of public and private drainage. But how to apportion the expense has been left undecided by the Committee; as has also been the other important point, of how best to secure combination and co-operation among the different Boards.

There is also a great difficulty in fixing the limits of indirect advantage where there is no underground communication with the sewers. For instance, in the Holborn and Finsbury Trust, the inhabitants of the high lands about Hampstead and Highgate are exempted from the payment of sewers' rates, although they are, unquestionably, benefited indirectly by the sewage of the lower districts between them and the river, which are forced to provide a passage for their superabundant waters. But a Court of law has decided that they are not liable, and no rate has been levied by the Commissioners for many years, beyond a certain line.

The sewers' rate is regarded as a landlord's rate, but is paid, in the first instance, by the occupying tenant. It would be expedient, where there is not a special agreement to the contrary, that a receipt given by the Commissioners to the tenant should be in all cases a legal set-off against the rent; while houses untenanted for any length of time, and consequently not contributing to the wear and tear of the sewers, should be allowed a temporary exemption from the rate. This improvement would be a great relief to the inhabitants, as by the existing law the houses are liable for the rate, without regard being had to the recent entrance of the occupants, or the length of time a particular house has been unoccupied.

Whatever doubts exist as to the jurisdiction of the Commissioners should be completely removed. Power should be given them, in all cases, to cover in, enlarge, widen, or otherwise improve open sewers; to compel builders to provide new districts with adequate com-

munications with the main lines of sewers; to rate old property for the construction of new sewers; and to oblige the owners of all houses thus rated to form communications with the sewers when built.

It was estimated by the late Mr. Rennie, prior to the general Macadamizing of the streets, which has much increased the amount of muddy heavy matter, that the daily discharge of the several sewers entering the Thames, within the sewer districts, amounted to 1500 tons per day; with the subsequent increase of population, and the alteration in the paving above alluded to, the present discharge of mud cannot be less than 2000 tons daily, which, notwithstanding the immense quantity of water by which it is accompanied, would appear (did not experience show the contrary) to threaten serious consequences to the navigation of the river.

(851.) With regard to the construction of, or the mechanism employed in, the operation of the sewers, there is little that calls for particular illustration; they are generally constructed of brick in regular cylinders of different diameters, from 3 to 5 feet or more, and are formed where practicable by opening the ground above them, and where necessary by a gallery, as in mining; they are laid at a depth of from 16 to 20 feet below the surface, and therefore descend gradually towards the river, which they enter a little above low water. In some cases, however, particularly on the South side of the Thames, where the sewer can have but little inclination, and is for a considerable distance even below high-water mark, it is necessary to have sluices carefully formed near the mouth to regulate the discharge of the sewer, and to prevent the tide water from ascending it, which would not only produce great mischief by flooding certain parts, but would be liable to blow up the sewer itself. To prevent this the sewer at the place of the sluice is constructed in strong masonry, and two shafts are formed under the sluice-house, one leading to the penstock, which regulates the discharge of the sewer, and the other to the flap which is used to prevent the tide water entering, and which is therefore shut at a proper time of the tide. The latter is a heavy strong circular plane, formed of iron-bound timber, exceeding the interior diameter of the stone sewer, and suspended on heavy hinges above, so that by its own weight it would hang down and close the sewer against the rising tide, but it would also, if left thus, impede the discharge of the sewer at low water; a strong chain is therefore fixed at its lower part, which is made to pass over a guide-pully a few feet in front and a little above the level of the hinges; the chain passes thence to a barrel and winch in the sluice-house, and by means of which it is opened or closed by the sluice-keeper at the proper times of the tide.

The penstock, which is a few feet behind the flap, is also worked by the sluice-keeper in the sluice-house. This is commonly of iron, and with its guide-frame is of very considerable weight, so that, in order to enable one man to work it, great mechanical advantage is obliged to be given. In some cases the winch is made to turn a bevelled wheel whose axle is horizontal, and this to turn another such wheel whose axle is vertical, to which a strong vertical screw is fixed; and this screw working in a nut in the penstock frame rises or depresses is according to the necessity of the case. The shafts to which we have alluded are left open, and furnished with proper ladders, in order to descend and repair or rectify any part of these underground Works when required.

Manufac-
tures.Water
Works.

Water Works.

(852.) This is a term usually applied to those hydraulic Works by which large towns and cities are supplied with water for domestic uses from some distant source; and to the extensive adoption of such Works we may probably greatly attribute the general healthy state of the immense number of human beings so closely congregated as they are found to be in the Metropolis, and in many other towns in this Kingdom. The Ancients were very deficient in this Art; they are said to have been unacquainted even with the important fact that water in a continuous pipe will always attain to the same height at its two extremes, if not impeded by confined air or some other impediment; and that they, therefore, only conducted their water in pipes down hill, but never carried it up again. This, however, has been questioned; that they did not conduct their water to any extent up hill is admitted, but not from being unacquainted with the principle, but for want of proper materials for the construction of their pipes. The Moderns, however, carry their water along hill and dale to any distance from the original source, distributing it, at the same time, in any lateral direction at pleasure, while the Romans and other ancient nations, either from a want of theoretical knowledge or practical means, could only receive their supply of water from some source higher than the part to which it was directed, and, therefore, if any valley interposed between the two places, very extensive Works became necessary to furnish a passage for the water. These were called aqueducts, and several splendid remains of such Works are still to be seen in many places both in Europe and Asia.

Ancient
and modern
aqueducts.

A very lofty and extensive Work of this kind is still existing in the environs of Constantinople, and remains of others are to be found in Italy and other Countries. The Moderns have also their aqueducts, but they are generally subterraneous, and of much less magnitude than those of the Ancients. Belidor states, in his *Architecture Hydraulique*, that one of the finest subterraneous aqueducts in France is that of Arcueil, three miles from Paris, constructed in 1624, which conducts water from many collecting channels into one large channel of stone. This aqueduct is 14,920 yards in length, and is constructed of freestone; it extends from the valley of Arcueil to an elevated water cistern or *château d'eau* which is at the port of St. Jaques. The channel has an inclination of 6 inches in 400 yards, or of 1 yard in 2400. On each side of the water-course is raised a foot-path 19 inches wide, upon which a person can walk as far as the village of Arcueil. The height of the passage from the bottom of the water trough to the under side of the arch is $6\frac{1}{2}$ feet, except in some places, where it has been necessary to keep it lower in consequence of the high roads passing above it.

Many other subterraneous Works of this kind are found in different parts of France, as also some of modern construction, which are elevated in traversing the valleys they meet with in their course, the most remarkable of which is that erected in the time of Louis XIVth, to conduct water to Versailles and Marly. One of these is the aqueduct of Maintenon. It consists of three courses of arches raised one above another, to support the water-course, which is a channel of stone, and on each side of it a narrow path with a parapet which renders it safe to walk along the side of the aqueduct when it requires cleansing or repair. There is

a description of this Work in the *Philosophical Transactions* for 1726 and for 1728, while it was in progress, and of which abstracts are given in vol. iii. of the Abridgment by Dr. Hutton, pages 187 and 231. From these it appears that this aqueduct is 2560 fathoms in length, and consists of 242 arches; the span of each $6\frac{1}{2}$ fathoms, and the thickness of each pillar, to sustain the arches, 4 fathoms; on the side of the valley next to Maintenon there are 33 single arches, afterwards 71 double ones, that is, having one arch upon the other; then 46 treble ones; at this part the water-course is generally 216 feet 6 inches high from the ground up to the floor of the water channel; afterwards there are 72 double arches, then 20 single ones, which last reach to a mound of earth, which is raised 50 feet high above the ground for a great distance.

Mechanical
Processes.

The general height from the ground up to the second arcade or row of arches is 16 fathoms; from the second row to the third or upper arcade 14 fathoms; in the upper arcade the arches are double the number of those they stand upon; above this it is 6 fathoms 6 inches more to the floor of the channel, which is, at least, 7 feet high besides the parapet. The pillars at the ground are 8 fathoms thick, but, with the slopes and shortenings which are made in every story, the top, where the channel runs, is reduced to 20 feet broad. There is likewise at each pillar a buttress projecting 1 fathom and 2 fathoms wide to strengthen the pillars.

There is another great aqueduct raised on arches in the Plaine de Bue, which conducts water to Versailles from the Plaine de Scale. This is built with 2 ranks of arches, and the lower ones are so much wider than the upper, as to afford room for a carriage-way across the valley about half as high up as the water-course. Drawings of these great Works are given by Belidor. The aqueducts of Great Britain are of a different character to those of either the Roman or the French above spoken of, except, indeed, we consider the New River in that light, which in its object is nearly of the same kind, viz. the supply of water for domestic uses; but this differs much in its general character from the above, while our other aqueducts have for their object, not the supply of water, but to furnish a means of water transit for our minerals and manufactures; and of these the most remarkable in this Country, perhaps in the World, are those of Pontcysylte and Chirk in North Wales, constructed by the late eminent civil engineer, Mr. Thomas Telford.

In this Section we shall confine our illustrations to those Works only of which the object is the supply of water for the general uses to towns and cities, and which in their main principle involve no very intricate mechanical process, although the theory of such Works is by no means obvious, and has, accordingly, engaged the attention of many of our most eminent civil engineers. To determine the quantity of water that will be delivered from a given aperture under a given head or pressure, when that aperture and head are contiguous to each other, is a direct question of computation, resting on the well-known laws of gravity; but, if the aperture of discharge be at any considerable distance from the head, a new question, and one resting immediately on experiment, arises, viz. the amount of friction and resistance of the water in its passage against the sides and bottom, if the canal be an open one, or against the inside of the bore of the pipe if an enclosed one. Moreover, in the latter case, the close pipe may ascend and descend in

Modern
Water
Works.

Manufactures.

its course, and this will again considerably affect the amount of delivery. It is obvious, therefore, that the theory of Water Works involves many considerations which must rest, in a great measure, on practical experience, and this has led several eminent engineers and mathematicians to prosecute long and interesting series of experiments on the discharge of fluids under all variety of circumstances. The greater number of these have, however, been recorded in our elementary Treatises on Hydraulics and Hydrodynamics, so that it only remains for us here to give a concise sketch of the history of Water Works in this Country, the amount of water thus supplied to the people, and a general indication of the mechanical means by which this supply is so largely and conveniently distributed. Such Works are found in all large populous towns in the Kingdom, but those which supply the Metropolis are by far the largest and of most general interest; and, as the principle of operation is necessarily nearly the same in all, we shall confine ourselves mostly to these.

General description of Water Works.

When a town is so situated that the source from which the water is obtained is above the highest point at which the water is required to be delivered, the Works are, of course, very simple. It is only necessary in such case to form artificially, if it does not naturally exist, a sufficient reservoir rendered water-tight at the bottom and sides by puddling or otherwise, to conduct from this reservoir large water mains into the principal parts of the town, and from these mains to lay on branch pipes to the points where the water is to be delivered. In such a case as this where there is no lack of a sufficient supply, the mains may be kept constantly charged, and a cock at the point of delivery, to shut off the discharge when the water is not wanted, is all the Works consist of. But when there is not such an abundant supply, then it is necessary to have means to shut off the water from one part of the town while it is sent to another part, and as, in this case, water cannot at all times be obtained from the delivery cock, a cistern is generally used by the inhabitants to catch such a quantity of water, while it is laid on, as is sufficient to supply their wants during the time it is diverted to another direction. And, to prevent loss from the negligence of the parties supplied allowing their cisterns to overflow and the water to run to waste, these cisterns are, frequently, each supplied with a ball-cock. The ball floating on the water and being thereby lifted with the water surface, and being, at the same time, connected with the handle of the cock, it gradually closes the aperture as it rises, and at a proper height shuts it entirely; but, as the water is drawn from the cistern, the ball again sinks by its own weight and the aperture is re-opened.

From a low source.

These are nearly all the means that are required in cases where the supply is higher than the point of delivery; but when the supply is below, as in the case of a town being supplied from a river running through it or in its vicinity, then additional Works become necessary to raise the water from its lower level to some elevated reservoir, formed on high ground in the neighbourhood, or on the top of some building, thence called a *water-house*, having a large cistern on its top, whence a sufficient pressure may be obtained to direct the water to its several points of delivery. In the latter case, as the reservoir is necessarily limited in dimensions, it must be constantly supplied as the water is drawn off, which, consequently, requires more management and attention than in the former.

Sometimes, also, a certain number of houses or points of delivery are above the level of the highest reservoir; in this case, if the aperture leading to the reservoir were closed and the water forced by the engine, it would, of course, ascend to the points required, but if any excess of pressure were exerted there would be great danger of bursting some of the pipes. To prevent this, a very ingenious contrivance is had recourse to; this consists in a standing pipe, 20, 30, or more feet above the surface of the reservoir, open at top, or returning again in the siphon form. This pipe is connected with the pipes of the upper supply, and it is obvious that, as soon as the pressure exceeds what is due to this head, the water will flow over the top of the pipe into the reservoir below, and thus act as a safety valve to the general system. The means had recourse to for raising the water from the river, well, or low supply, to the reservoir, may be any mechanical agent we have at command. In the smaller Works the forcing pumps may be worked by horses, or, when circumstances admit, by a water wheel placed under a fall of water, or even by the running water of the river itself; but in all larger Machinery the steam engine is our only resource.

Mechanical Processes.

Standing pipe.

Machines for forcing.

Formerly, the pipes which formed the mains were of wood, bored, one end of one pipe being made tapering to be inserted into the larger and thicker end of the other; but, with these means, the pressure that could be employed was very limited. At present by far the greater number of Water Works have iron pipes, some with flanges at each end, which are securely screwed together with lead or other matter interposed between them, to render them water-tight. But more commonly now the iron pipes are inserted one within the other, like the old wood-pipes; for experience taught engineers that a long and continuous pipe, securely screwed together, exceeding about 300 feet in length, would pull itself to pieces by the contraction of the iron from the change of temperature between summer and winter. This change from wood to iron ensures two points, both of great importance, namely, an uninterrupted passage for the water, and great durability.

Wood and iron pipes.

Such is a sufficient illustration of the general principle by which these Works are conducted; we shall now make a few remarks on the progress they have been gradually making in this Country, from the first feeble attempts to the present powerful means and abundant supply of this element, so essential to the comforts, conveniences, and general health of the inhabitants of populous districts.

(853.) *Water Works for the supply of the Metropolis.* —The first attempt at supplying London with water does not seem to have taken place till the time of Elizabeth, in 1581, when a lease was granted by the Lord Mayor and commonalty of the City of London, of the first arch of London bridge, to erect an engine for the purpose of supplying the City with water. The lease was granted for 500 years. In 1583 another lease for 500 years was granted of the second arch for the like purpose. In 1701, a third lease was granted of the fourth arch for 381 years. In 1761 the third arch was granted on lease for 321 years; and, lastly, another lease was granted in 1767 of the fifth arch on the north side and the second arch on the south side, for 315 years. These leases, however, together with the Works, have been wholly cancelled and removed by the construction of the new bridge.

First London Water Works.

What were the nature and power of these Works during

Manufac-
tures.
Description
of the Lon-
don Water
Works as
they were
in 1731.

the period between 1581 and 1731 cannot be now ascertained, but in the *Philosophical Transactions* for 1731 we have a very interesting account of their state at that time, by Mr. Beighton, whose name has already occurred in our History of the steam engine. The Works themselves, as they then existed, were erected at the granting of the third lease, by Mr. Sorocold, and deserve notice, on account of a contrivance had recourse to for raising and falling the water-wheel to accommodate it to the different heights of the water. This was the invention of a Mr. Hadley, who put up the first of the kind at Worcester, for which he obtained a patent.

It appears, from the account above alluded to, that the wheels were placed under the arches of the bridge, and were moved by the common stream of the tide water.

The dimensions are stated to have been as follow: length of the axle of the wheel 19 feet, diameter of axle 3 feet, 8 rings each, 4 arms, 26 floats, length 14 feet, depth 1 foot 6 inches.

The axle rested on two gudgeons, in brasses, or two large levers, which were placed in a horizontal position, and therefore supported the weight of the wheel. The wheel by these levers might be made to rise or fall with the tide in the following manner. The levers were 16 feet long, divided by the fulcrum at 10 feet from one end and 6 feet from the other. At the extremity was a sector or arc of a circle, described from the fulcrum of the lever, and to the bottom of this arch was fixed a long triple chain made on the same principle as a watch chain, but the links were arched to a circle of 1 foot diameter, with notches or teeth to take hold of the leaves of a pinion of cast iron, 10 inches diameter, with eight teeth in it moving on an axis, which was fixed up over the arch, at a considerable height, and the chain went up to the pinion and turned over it. The other loose end of this chain had a large weight hanging at it, to help to counterpoise the great weight of the water-wheel, which prevented the chain from sliding on the pinion. On the same axis as the pinion was fixed a cog-wheel, 6 feet diameter, with 48 cogs. To this was applied a trundle, or pinion, of six rounds or teeth; and upon the same axis was fixed a second cog-wheel, of 51 cogs; lastly, this was turned by a trundle of six rounds, on whose axis was a winch, or windlass. The other lever was provided with a similar chain and wheel-work, and the axis of the last-mentioned trundle was prolonged until the two winches nearly met, so that one man, with the two windlasses, raised or let down the wheel, as there was occasion, to dip always equally into the water.

By means of this Machine, the strength of an ordinary man could raise about 50 ton weight, which much exceeded the weight of the water-wheel.

Near each end of the great axis of the water-wheel a cog-wheel was fixed, 8 feet diameter, and 44 cogs, working into a trundle of $4\frac{1}{2}$ feet in diameter, and 20 rounds, whose axis or spindle was of cast-iron, 4 inches in diameter, lying in brasses, at each end supported by strong timber framing.

And, because the fulcrums of the levers above described were in the line of the axis of the trundle, in what situation soever the water-wheel was raised or let down, the great cog-wheel was always equidistant from the trundle, and worked or geared therewith.

A quadruple crank of cast-iron was attached to the end of the axis of the trundle, the metal being 6 inches

square; each of the necks were distant 1 foot from the centre of motion; the gudgeons of the cranks were sustained in brasses at each end in two headstocks, fastened down by caps. One end of this crank was placed close abutting to the end of the axis of the trundle, which at that end was 6 inches diameter, and had a slit in the end; the crank terminated in the same manner, and an iron wedge was put, one half into the slit in the end of the axis, and the other half into the slit in the end of the crank, by which the axis turned the crank about with it.

Each of the four necks of the crank had an iron spear or rod joined to them, and also jointed at the upper end to its respective lever, within 9 feet of the centre of the lever. These levers were 24 feet long, moving on centres in the middle of their length, and supported by the frame. At each end of each lever was jointed a rod, which descended into the pump barrel, and had the forcers fastened to it. Each end of the four levers worked a quadruple forcing-pump, which consisted of four cast-iron barrels or cylinders, $4\frac{1}{2}$ feet long, 7 inches bore above, and 9 inches below, where the valves were placed; the four barrels were fastened by screwed flanches over four holes in a hollow trunk of cast-iron, which had four valves in it; just over these holes, at the joining on of the bottom of the barrels at one end of the hollow trunk, was a sucking-pipe and grate, going into the water, which supplied all the four pumps alternately, when they sucked or drew up water.

To carry away the water which they forced out, there proceeded from the lower part of each pump-barrel a neck, turning upwards arch-wise, whose upper part is cast with a flanch, to screw up to the under side of another square trunk, which received the necks of all the four barrels; which necks had bores of 7 inches diameter, and over the holes in the trunk, communicating with them, were placed four valves at the jointings or flanches. The square forcing-trunk was cast with four bosses, or protuberances, standing out against the valves, to give room for their opening and shutting; and on the upper side of the trunk were four holes, stopped with plugs, to take out on occasion to cleanse the valves. One end of this trunk was stopped by a large plug, and to the other the iron pipes were joined by flanches, through which the water was forced up 120 feet, or to any height or place required.

Besides this four-barrelled pump, there was such another placed at the other ends of the levers; but to avoid repetition, we have spoken only of one quadruple pump, as the other is just the same; but its rods or forcers being at the opposite ends of the levers, the barrels draw and force alternately.

At the other end of the water-wheel was placed the same sort of work as at the end already described; viz. the great cog-wheel and the trundle fixed upon the spindle or axis, which is united, as before mentioned, with the axis of the quadruple crank.

Also the four rods from these cranks to work the four horizontal levers, each of which had a forcer at both ends, to serve the barrels of a quadruple pump at each end of the levers; so that one single wheel worked sixteen pumps, viz. two quadruple engines at each end of the axis.

The following is Mr. Beighton's calculation of the effect.

"In the first arch next the City was one wheel, with double work of 16 forcers.

Mechanical
Processes.

Manufactures.

Beighton's calculation of the quantity of water raised in 1731.

" In the third arch	First wheel, double work at one end and single at the other .	12
	Second wheel in the middle...	8
	Third wheel	16
		In all 52 forcers.
" One revolution of a wheel made in every forcer		2½ strokes
" So that one turn of the four wheels made		114 strokes
" When the river was in the best state, the wheels went six times round in a minute, and but 4½ at middle water		6
" The number of strokes in a minute . . .		684
" The stroke 2½ feet, in a 7-inch bore, raises		3
		" Per minute 2052 gallons.

" That is, 123,120 gallons = 1954 hogsheads per hour, and at the rate of 46,896 hogsheads in a day, to the height of 120 feet."

This is the utmost quantity they could raise, supposing there were no imperfections or loss at all.

" But it is certain, from the following considerations, that no engine can raise so much as will answer the quantity of water the cylinder contains in the length of the forcer or piston's motion; for, First, the opening and shutting of the valves lose nearly as much of that column as the height they rise and fall. Secondly. No leather can wholly prevent water continually escaping when it is raised to a considerable height; and when the column is short it will not press the leather enough to the cylinder or barrel; but, especially at the beginning or first moving of the piston, there is so little weight on it, that before the leather can expand there is some loss. Thirdly. This loss is more or less, as the pistons are looser or tighter leathered. Fourthly. When the leathers grow too soft they are not capable of sustaining the column to be raised. Fifthly. If they be leathered very tight, so as to lose no water, then a great part of the engine's force is destroyed by the friction."—*Philosophical Transactions*.

By some experiments which Mr. Beighton accurately made on engines, whose parts are large and very well executed, they were found to lose one-fifth, and sometimes one-fourth of the calculated quantity. The imperfections or errors of engines, however, are to be compared together by the calculated quantities or forces; for, as they differ in these, they will proportionally differ in their actual performances.

The power by which the wheels were moved is as follows:

The weight of the column of water on a forcer 7 inches in diameter, and 120 feet high.

$$7 \times 7 = 49 \text{ pounds average in a yard nearly } 40 \text{ yards high}$$

$$\frac{1960 \text{ pounds on one forcer}}{8 \text{ forcers always lifting}}$$

$$\frac{\text{The whole weight on the engine at once}}{15,680 \text{ pounds} = 140 \text{ hundred weight} = 7 \text{ tons weight.}}$$

Then the crank pulls the lever 3 feet from the forcer, and 8.3 feet from the centre.

$$\frac{7 \text{ tons}}{\times 11.3}$$

$$8.3)79.1(9.5 \text{ tons on the crank.}$$

$$\begin{array}{l} \text{Wallower } 2.2) 9.5 \text{ (4.3 on the trundle)} \\ \text{The spur wheel } \dots 4 \end{array}$$

Mechanical Processes.

$$\frac{\text{The radius of the great wheel } 10)17.2(1.72 \text{ ton}}{20}$$

$$\frac{\text{The force of the floats } 18 \text{ hundred weight, } 40 \text{ pounds}}{34.40 \text{ cwt.}}$$

But, to allow for friction and velocity, may be reckoned 1½ ton.

$$\frac{\text{The ladles or paddles } 14 \text{ feet long, } 18 \text{ inches deep } \dots}{22.4 \text{ square feet}}$$

$$\frac{\text{The fall of water sometimes } 2 \text{ feet}}{44.8}$$

$$\frac{6 \text{ gals. in a cubic foot}}{268.8}$$

$$\frac{10 \text{ pounds in a gallon}}{112)2688(24 \text{ hundredweight.}}$$

The velocity of the water 4 feet in 21" of time; 21" : 4 feet :: 60" : 685 feet per minute.

The quantity expended on the wheel, according to the velocity of the stream, 1433 hogsheads per second.

But at the velocity of the wheel 645 hogsheads per second. The velocity of the wheel to the velocity of the water at 1 to 22".

Mr. Beighton makes the following observations on these Water Works: Beighton's remarks.

" Though they may," he observes, " be justly esteemed as good as any in Europe, yet there are some things which might be altered very much for the better.

1. " If, instead of 16 forcers, they worked only 8, the stroke might be 5 feet in each forcer, which would draw a great deal more water with the same power on the wheel; for then there would be but half the opening and shutting of valves, consequently but half that loss; and a five-foot stroke draws above double the quantity of 2 strokes of 2½ feet each by nearly one-fifth, as the velocity is double, which is the most valuable consideration in an engine where the pipes will sustain such force.

2. " The bores that carry off the water from the forcers are too small, there being nearly always two columns of 7 inches diameter forcing into one pipe of the same diameter.

" Therefore, those pipes of conveyance should be nearly 9 inches in diameter.

" The timber work is all admirably well executed; and the composition and contrivance, both for strength and usefulness, not exceeded by any.

" The cranks of cast iron are better than of wrought iron; by reason they are very stiff, and will not be strained, but sooner break; and then they are cheap, and new ones easily put in.

" The wedge for putting on, or releasing the crank and forcers, is better than the sliding sockets commonly made use of.

" The forcing barrels, trunks, and all their apparatus, are very curiously contrived for putting together, mending, altering, or cleansing, and subject to as little friction as possible in that part.

" The machine for raising and falling the wheels is very good, though but seldom used; for they will go at almost any depth of water, and, as the tide turns, the wheels go the same way with it.

" These machines at London-bridge are far superior to those so much famed at Marly, in France, as the

Manufac-
tures.

Smeaton's
Report of
those
Works in
1763.

latter are very ill contrived in the cranks and some other parts."

Such is Mr. Beighton's account of the state of the London Bridge Water Works in 1731; but, in 1763, when the two middle arches of the Bridge were thrown into one by the removal of the pier, the water-way of the river was so much increased that the water-wheels did not perform the same duty as formerly, the amount being reduced to 2716 hogsheads every twelve hours; and it was in consequence of this reduction that the City granted their lease of the fifth arch, for which Mr. Smeaton planned a larger Machine than any of the others. This was erected in 1767, and is described in vol. ii. of the Reports of this distinguished engineer. The several dimensions were as below:

	ft.	in.
Diameter of water-wheel to the extremity of the floats	32	0
Diameter of ditto in the rings, out and out	27	0
Width of wheel, or length of the floats . .	15	6
Number of floats, 24.		
Width of each	4	6
Diameter of spur wheels in the	14	0
Number of cogs, 80.		
Number in the lantern, 23.		
Diameter of water-wheel gudgeons	0	7
Length of cylindrical part	0	7

Notwithstanding this and other additions, and the aid of a steam engine of the old form, (then commonly called a fire engine,) for forcing the water when the tide was very low, and which existed prior to Smeaton's last Work, yet the supply was not all that could be desired; and Mr. Smeaton, being desired to examine the subject, reported that,

"Having carefully examined and considered the construction of your engine, I am of opinion that as, in the present situation of the pipe for supplying the well, the engine cannot have a sufficient quantity of water at low water, I entirely approve of the proposition for laying a horizontal suction pipe, in order that the engine may take the water immediately out of the Thames."

At present, he observes, the whole water is raised by the fire engine to the top of the (water) tower 120 feet, although it most commonly happens that one-half, two-thirds, or three-fourths of that height would be sufficient; and he, therefore, recommended to unite the main from the fire engine with those of the water machine, by which means the fire engine would be relieved of that unnecessary pressure, and, like the water machine, would only be exposed to the pressure on at any time.

These plans, and other subsequent improvements, were made at times, as repairs became necessary; and, in 1821, when a Parliamentary Inquiry took place relative to the different Water Companies in the Metropolis, it appears that the London Bridge Water Works then supplied 29,516,333 hogsheads per annum, and that the number of houses supplied was 32,071, and the annual rental, £35,358.

These Works, so interesting from their early commencement, and from their peculiar Machinery, we have described at some length, and have carried their history through from their commencement to their final removal, although many other important Works were formed during this long period, which ought, perhaps, to have been introduced into our notice between the in-

tervals of the several improvements we have pointed out in the above Works. We have preferred, however, speaking of each separately.

(854.) *New River*.—This important undertaking dates but little later than the second London-bridge lease, having been commenced in 1608, under the authority of Government, with power to bring a new supply of water to the City from certain streams or springs in Middlesex and Hertfordshire. After these powers were granted, various attempts were made, but all of them were abandoned on account of the difficulty and expense attached to such a vast concern. At length, the City made over to Mr. Middleton and his heirs all the power and rights conferred by Parliament, and he began the business at the date above specified. Two springs, one rising near Ware, and the other at Amwell, in Hertfordshire, were united for the supply of an artificial river, which was conducted to the Metropolis. The expenses of the undertaking, however, were so great that they exhausted the fortune of the projector; who, having in vain applied to the Corporation of London for assistance, at length procured it from the King, (James I.) to whom half the share of the concern was made over in consideration of his taking an equal share in the expense.

On September 29, 1613, the water was let into the New River Head at Islington, but the projector was ruined by the expense; and it was long afterwards before the scheme was rendered useful and beneficial to the Public.

The New River is, as above stated, formed by the collected waters of springs which rise in Hertfordshire, about 20 miles from London. These are collected into a large open basin of considerable depth, near which a stone is placed with inscriptions, implying that the stream was opened in 1608, and that from Chadwell Spring the river flows by its windings 40 miles. The original supply of water having been inadequate to the consumption, the mill stream of the river Lea, which runs near it, was resorted to; and, after various disputes and litigations between its proprietors and those of the New River, the mill has at length become the property of the latter Company, who have now an unrestricted use of the water, so that the river Lea may be considered as one of the sources. On a sluice leading from it are flood-gates, with a building, in which a man is placed, whose constant employ is to raise or lower them according to the fulness of the river below; and that he may not err in the quantity supplied, a gauge is fixed across the sluice consisting of a stone of great bulk, under which all the water passes, so that the current is regulated with the greatest exactness. To preserve a proper slope, (3 inches in a mile,) the New River takes such a winding course that the length of the channel is above 39 miles. Passing Ware, Amwell, Hoddesdon, and Cheshunt, it enters Middlesex near Waltham Cross; bending towards Enfield Chase, it turns to the town of Enfield; and, at Bush Hill, was formerly carried across the valley in a wooden aqueduct, or open trough, 660 feet in length, supported by arches; but the improvement in canal-making has suggested a better mode to effect the purpose by means of a mound of earth, over which the river passes in a new channel, which was completed in the year 1785. Hence the river proceeds with devious bends to Hornsey, between which village and Highbury it was formerly conveyed in another wooden aqueduct, now superseded like the

Mechanical
Processes.

New River
Works.

New River
described.

Manufactures.

former by a bank of earth. Still winding, it reaches Stoke Newington, and passes on to the East side of Islington, where it has a subterraneous channel for 200 yards beneath the street. Just before this part is a building, whence several mains or pipes are sent to supply the Eastern side of London. After passing under the road, the New River emerges and coasts the Southern side of Islington, till it reaches its termination at the grand reservoir, called the New River Head. The width of the river near Islington is $14\frac{1}{2}$ feet, the average depth $4\frac{1}{2}$ feet; but the depth decreases on descending towards its source. The number of bridges which cross the river in its whole course is about 200. In various places are sluices to let off the waste water, which, with other Works, excited admiration in the earlier stage of this branch of Mechanics, but are now overlooked in the wonder of canal navigation. The contrivances for distributing the water through various parts of London are also very admirable. From a circular basin, now thrice its original size, which first receives it, the water is conveyed by sluices into several large brick cisterns, whence it passes through large pipes to the several districts, and is conveyed into the houses by leaden pipes. At the New River Head is a building containing two steam engines and a water engine for forcing the water to a higher reservoir near Pentonville, and to another near Tottenham-court-road, for distribution to the Western parts of the town. Near the former reservoir, in a field, is an iron safety pipe, 12 feet high, and 4 feet 8 inches in circumference, with a wooden tub placed on its top, which acts in the double capacity of an air and waste water pipe, and is useful in preventing the bursting of the pipes, which was formerly very frequent from the force of water, or from compressed air.

Shares of the Company.

The property of this great Company was originally divided into seventy-two shares, of which thirty-six were vested in Sir Hugh Middleton, who was obliged to part with them to various persons: these are termed Adventurers' Shares. The other thirty-six were vested in the Crown for the money advanced by King James towards the undertaking. These were alienated by Charles I., and are termed King's Shares; but, as the Crown had no concern in the management, so the holders of these shares are excluded from the direction. The original value of the shares was £100 each, but so discouraging were the first prospects that they fell to a very low price. At present they are worth a hundred times their original value; a rise in property scarcely to be paralleled, and demonstrative of the increase of buildings in the Capital. The management of the Company's affairs is vested by Charter in twenty-nine holders of Adventurers' Shares, who form a Board. The officers are, a governor, deputy governor, a treasurer, and a clerk. Few public Companies surpass this in property and extent. The constant repairs and improvements employ a vast number of men and horses; and the whole system of the distribution of the water is so complicated as to require the utmost skill and attention on the part of the surveyor and other officers.

It appears that the New River Head is $84\frac{1}{2}$ feet above the Thames; and, consequently, a great part of the water supplied requires no Machinery. Some houses, however, are situated above this level, and to supply these a higher reservoir is required. In the first Works the water was forced to this level by a windmill. A horse-mill was afterwards employed prior to 1767; (pro-

VOL. VIII.

bably about 1737;) this was supplanted by a steam engine; and this again was replaced in 1787 by one of Bolton and Watts's. The number of steam engines employed at these Works in 1820 was three, of sixty-three horse power. The following document, however, submitted to the Committee of the House of Commons in 1821, will give a much better view of the extent and importance of this Work than any detached statement we can make; and it will, we are convinced, be very interesting to the curious reader.

(856.) *The Chelsea Water Works* were commenced in 1732, by authority of Parliament, the number of original £20 shares having been 2000, but, in 1734, 2000 other £10 shares were issued. This Company draws its supply from the Thames, and has consequently to raise all its water by steam power.

The quantity of water supplied by these Works in 1820 was 7,533,900 hhds.
Number of houses supplied 8,632
Annual water rental £12,586

East London Water Works.—These are the next in importance to the New River Works.

The quantity of water supplied by these Works in 1820 was 29,516,333 hhds.
Number of houses supplied ... 32,071
Annual rental £35,358

Grand Junction Water Works:
The quantity of water supplied in 1820 13,104,000 hhds.
Number of houses supplied ... 7,180
Annual water rental £20,468

West Middlesex Water Works:
The quantity of water supplied in 1820 11,904,100 hhds.
Number of houses supplied ... 10,350
Annual water rental £25,915

The grand total of all these, including the old London Bridge Water Works, was, therefore, in the above year,

155,381,038 hogsheads of water.
120,000 houses.
£175,890 water rental.

Since the above period, great changes have taken place in the amount supplied from the different Companies, in consequence of the removal of the London Bridge Works, as will be seen as we proceed. We have spoken above only of the Water Works on the North side of the Thames: besides these there are three Companies on the South side, i. e. the Lambeth Company, the South London Company, and the Southwark Company, the amount of which supplies was not stated in the Report of 1820.

(857.) Another inquiry, however, took place in 1828, in consequence of the great complaint made by the inhabitants of those parts of the town which received their supply from the Thames, the water of which, never very pure, is now rendered wholly unfit for any but the most common uses, from the great increase of common sewers, and the refuse of gas and other Works, which are daily discharged into the river. Petitions were accordingly presented to Parliament, and a Committee of the House was appointed in July of that year to inquire into the matter. This Committee, after examining several scientific men, and inquiring into the system pursued by the different Water Companies, made their Report to the House; in which they stated it as their opinion, "That the then present state of the supply to the Metropolis was susceptible of and required great improvement, and that many of the complaints relative to the quality of water were well founded, that the supply ought to be derived from other sources than those then resorted to, and that it should be guarded by such restrictions as would at all times ensure the cleanliness and purity of an article of such prime necessity;" and the Committee further recommended

Mr. Telford's proposed improvements in the London Water Works.

Manufac-
tures.

that Mr. Telford should be instructed to make such surveys as he should think necessary in order to enable him to recommend a practicable and efficacious plan for supplying the whole of the Metropolis with pure and wholesome water. This recommendation, however, was not acted upon by Government authority till March, 1831, and even then not till Sir Francis Burdett stipulated to exonerate the Public from any of the expense attending the operations; a pinching and unprofitable economy, which was afterwards abandoned by the Treasury upon the ground, "that it was the duty of the Government to give effect to the recommendation of the House of Commons."

Nothing, however, has yet been done towards practically remedying the evil, the inhabitants being

still supplied by six out of the eight Water Companies with water drawn from the impure source of the Thames. Another Committee has been formed, and Mr. Telford's Report presented, with a plan for supplying water from two rivers, one on each side the Thames. Before, however, referring more particularly to this proposition, we propose to give again an abstract of some Tables on this Report, relating to the quantity of water supplied daily by the different Companies in 1833 and 1834, which so far exceeds those of 1821 as would make them appear incredible if not given under such undoubted authority, amounting as it does in the aggregate to the extraordinary quantity of about 40,000,000 imperial gallons daily, as will appear from the following statement.

Cisterns generally 38 feet high, being the mean elevation at which the water is supplied.

The greatest elevation at which the water is supplied 60 feet.

Mr. Telford's Report.

(859.) In the course of his survey Mr. Telford examined the capabilities of the river Colne, which passes at Uxbridge, after having received at Rickmansworth the waters of a considerable stream called the Chesham. He found that, except after heavy rains, the Colne is an insignificant stream quite inadequate to the purposes required, and when swollen by rains that the water was unfit for domestic use on account of its muddiness; but about half way between St. Alban's and Watford the Colne joins the Verulam, a transparent stream which occupies the valley of the former town. At Watford mill, in 1833, being a remarkable dry year, the Verulam river produced 16,200,000 imperial gallons daily, a quantity, he considers, amply sufficient for the required purpose, although new buildings in the North-Western district should be added to a considerable extent, or as numerous as during the last twenty-five years.

About two miles above Watford the valley of the river affords a commodious situation for extensive reservoirs of water, and for allowing it to settle if such should be thought necessary. From this place, the projectors proposed to convey a covered aqueduct to descend with a uniform inclination of 18 inches per mile to Primrose Hill, North of the Regent's Park, terminating there in extensive receiving and distributing reservoirs at the height of 146 feet above the high-water mark of the River Thames. From these reservoirs each of the three Companies for supplying the North-Western district might be supplied separately, and in any proportions that might be determined upon.

To deliver the water into the reservoirs at Primrose Hill as pure as it leaves the Verulam, it is proposed to

convey it through a covered aqueduct, and at such a depth below the surface of the ground as to be secure from the effect of frost and from external injury, preventing also mixture with surface water. To remedy the inconvenience occasioned by cleansing and repairing, Mr. Telford proposes constructing the aqueduct with a double watercourse, separated by a footpath through its whole length; and to provide an adequate supply in the probable event of an increased population, he suggests that the aqueduct should be made sufficiently large to convey the whole quantity of 30 cubic feet per second furnished by the Verulam. The analysis of this water, which has been made by persons of the first Chemical eminence, as well as the adduced testimony of various persons residing in or near Watford, leave no room to object in any way against the purity and excellence of the water which it is thus proposed to bring to the supply of that part of the metropolis. The quantity of water required for the supply of the inhabitants South of the Thames is much less than that required on the North side, 10 cubic feet per second being stated as a quantity adequate to the purpose.

Mr. Telford proposes to supply this quantity from the river Wandle, at a sufficient elevation, found on the Croydon branch, at the East of Beddington Park, 90 feet above high water in the river Thames. From this place an aqueduct, similar in its construction to that above described, may be carried in nearly a direct line to Clapham Common, and there terminate in the requisite number of reservoirs at a height of 82 feet above the highest level of the Thames, and which, with the single exception of Brixton Hill, exceeds the height of delivery effected by any one of the three present Companies supplying this district.

The main branch of the Wandle takes its rise in a singularly copious spring, in the vicinity of Croydon, and after pursuing a Westerly course for about three miles is joined by the Carshalton branch, which likewise derives its origin from several plentiful springs in that neighbourhood. The water of this river possesses at all times an uncommon degree of purity, regaining its transparency after the heaviest rains in the course of a few hours.

The quantity of water flowing down the Carshalton branch of the Wandle in the extraordinary dry season of 1833 was at the rate of 13 cubic feet per second

**Manufac-
tures.**

while the quantity discharged by the Croydon branch was at the rate of 17 per second; there can, therefore, be no doubt of the adequacy of the source whence Mr. Telford has proposed to draw the supply of water necessary for the inhabitants of the Southern part of the metropolis.

It seems unnecessary here to go into any description of the means possessed for the same purpose, as regards the North-Eastern district, by the New River and East London Companies, both because it is not proposed to make any material or immediate alteration in their present arrangements, and because the necessary particulars may be gathered from other sources. There can be no reason for doubting the adequacy of the river Lea for the purpose of supplying, if such a necessity could arise, the whole Northern district of London; since we are told, on the authority of Mr. Telford, that in the month of November, 1833, the quantity of water flowing down that river was found to be 110 cubic feet per second, *after supplying the New River*. Some suggestions are made in the Report, by adopting which the original purity of the water of the Lea would be preserved more completely than at present; but a description of these plans involves merely technical details, which would hardly be interesting to our readers. It may, however, be well to mention, that the water of the Lea is originally of the same quality as that of Verulam, the sources of both being from the great chalk ridge which intersects Hertfordshire.

To effect the objects proposed by Mr. Telford, of conducting the waters of the Verulam and the Wandle for the supply of London, a considerable outlay of money would be required. An estimate of the cost of the various Works is given, showing an amount,

For the North side of	£785,965
And on the South side of . . .	391,875
Together	£1,177,840

a very large sum of money, undoubtedly, and which, being beyond the means possessed by the existing Companies, must in the outset be advanced by Government. This consideration should not, however, be allowed to stand in the way of accomplishing so important and necessary an object as the supply of wholesome water to the metropolis; and especially as means have been pointed out whereby the interest could be paid upon the outlay without adding in any way to the public burthens. The plan for this purpose was proposed by the Directors of the Grand Junction Water Works Company, and was to this effect: that the Government having advanced the sums required to bring the water to the spots whence the Companies could receive it into their respective Works, each of these establishments should pay its proportion of interest, according to the quantities of water respectively used by it, the rates of the Companies being pledged to the Government as security for the payment of the interest. On the other hand, it was proposed that the Companies should be authorized to make such an addition to the rates charged to their customers as would compensate them for this payment, taking into consideration that their constant annual outlay for pumping and filtration would be materially lessened by the adoption of the plans proposed. To this additional charge the Public could not fairly object, the advantage of securing a plentiful supply of pure water being sufficiently great to compensate for the

small additional charge that would be necessary for the purpose. (See Telford's Report.)

**Mechanical
Processes.**

Works relating to the Construction of Wharfs, &c.

(860.) The term Works is generally applied to the various preparatory steps towards the construction of wharfs, basins, canals, locks, &c., and we take advantage of this circumstance to describe in this place some processes or principles of construction which have been introduced into practice since our Articles Canal, Dock, &c., were written in the general alphabetical arrangement of this Work. These relate to the formation of wharfs and dock walls, &c. Hitherto, in forming the front of any wharf against a tide river, it was considered necessary to form what is called a coffer dam, by driving in front of the intended wall a double row of piles, and to throw and work in clay between the two rows, in order to keep out the water from an excavation made behind them, for laying in the foundation of the wall, and while raising it to the intended height; after this has been effected, and when every thing is completed, the piles which had formed the coffer dam are drawn up again, and the river admitted to the wall, the latter being properly defended by timbers placed there for the purpose.

These operations are, of course, attended with great labour and expense, and, with a view to avoid or reduce these, several ingenious engineers and architects have lately turned their attention to means of constructing wharfs and other walls without incurring such vast expense and labour. The plans proposed have been, first, to construct the wall by driving iron piles and to fit iron plates between these, so as to form the proper face; another, which has been proposed as a more substantial mode of proceeding, is to form the whole with iron piling; and a third method is to form the wall of a concrete which sets under water, and sufficiently solidifies to form a substantial wall in every respect resembling actual stone.

We have already, under the Article Pile Engine, referred to the two former of these propositions; the first being the projection and execution of R. Sibley, Esq., architect, Great Ormond-street, and the second by James Walker, Esq., civil engineer. We could not properly in that Article do more than refer to the two cases above mentioned, but we have, by permission of the latter gentleman, been furnished with a full description of a Work of the kind constructed at Blackwall, by Mr. George Bidder, who superintended it while in progress; and to whom we are much indebted for the very accurate drawings which are given on a reduced scale in plate lxxv.

Iron wharf at Blackwall.—The Directors of the East India Docks having resolved upon rendering a portion of the Dock premises facing the river, upwards of 700 feet long, a commodious quay for the accommodation of all descriptions of steam-vessels frequenting the port of London, a question arose as to the best mode of effecting this; viz., whether by jetties, or a continuous line of wharf, composed either of brickwork, iron, or timber.

The objection to the jetties consisted in this; that they must have projected considerably into the river to attain a sufficient depth of water for steamers to lay afloat at all times of tide, thereby interfering with the navigable part of the river by narrowing it.

Moreover, it is not very commodious, as being

Iron wharfs.

Manufactures.

necessarily removed some distance from the offices and sheds situated on the old wharf; while the transit of goods to and from the vessel would be exposed to delays and expenses of serious consequence to the rapid delivery required for much of the cargoes now conveyed by steam.

For these and other reasons the continuous line of wharf was determined on; and it only remained to decide on the material of which the wharf should consist.

A stone or brick quay wall is clearly the most substantial and durable; but, as above mentioned, it being a *sine qua non* that steamers should have the opportunity of coming and leaving at all times of tide, it could not be founded less than 12 or 13 feet under low water, Trinity standard, and to have done this would have required a very substantial coffer dam. The cost and time requisite to complete this, before a brick could be laid, would necessarily be so great that it was thought proper to endeavour to find a sufficient substitute.

The advantage of cheapness afforded by a wooden frontage was thought to be more than counterbalanced by the great current outlay which must shortly have ensued from its decay and great height, exposed to the effects of wind and water.

The Directors were therefore thus induced to try the experiment of constructing in this place an iron wharf.

The City being applied to granted permission to the Dock Company to extend their premises, on an average about 20 feet into the river. The locality of the line of frontage being thus settled, it afforded to Messrs. Walker and Burges the data upon which they adopted the principle of its construction.

For as the depth of water against the wharf, to allow steam-vessels to lay afloat at all periods of tide, could not be less than 11 or 12 feet, and the tide in the river Thames flowing 18 feet on a medium, and occasionally 3 feet higher, as in February of this year, the whole height of the wharf could not be less than 34 feet.

This at once decided the necessity of having an uninterrupted line of sheet piling at bottom, because the principle adopted in other wharfs, of inserting at regular intervals grooved piles and filling up between with plates, could not be applied here, inasmuch as that, before a plate could be fixed, the ground must be cleared away, and this would have infallibly destroyed the old wharf, as the excavation would have left its foundation exposed for a depth of 13 or 14 feet. Moreover, had this objection been surmounted, it would have been found that the expense of fitting these plates under low water, from the usual irregularities of casting, must have been very great.

In consequence, it was found necessary to adopt a practical plan of more general application.

To carry the piles the whole depth of the wharf, *viz.* 34 feet, without allowing for hold of ground, would have caused them to be very unwieldy and difficult to drive, as from greater length the chances of their being cast crooked is considerably increased; they would, in consequence, twist in driving, and if a strain was applied to keep them in their proper lines it would only bend them, and render the evil worse; further, their liability to break would be increased three or four fold. It was in consequence determined by Messrs. Walker and Burges to have a row of piles to a certain height, and the rest to be made up of main top piles and intermediate plates.

It was the opinion of many professional men that iron

piles could not be driven through soil so hard as that known to exist in the bed of the river in the neighbourhood of Blackwall, especially if in the line of wharf any of the well-known Blackwall rock should be encountered, this being a concrete of gravel and the oxide of iron, obtained from the land springs flowing through the gravel beds. This stratum varies from 6 inches to 18 inches in thickness, and though it is easily fractured when unsupported underneath, yet when resting on a solid bed of gravel it is very difficult to penetrate.

Experience, however, has proved that iron piles can be driven through this, as it was met with in several places, requiring, nevertheless, great care in driving. In one place, two of the main piles were broken before the stratum could be penetrated; the sheet piles, from the greater sharpness of their points, and less sectional area, were much more readily driven through it.

The length of the fall of the ram was restricted to four feet, and if the soil in any case was found to be more than ordinarily hard, from the shaking of the pile, or if any strain was requisite to be used to keep a pile to its lines, the blows were further reduced.

The jar of the blows was obviated by a board of elm, three-quarters of an inch thick, interposed between the head of the pile and the monkey; one of these boards, if of good stuff, and the pile-head fair cast, would frequently drive a pile its whole depth, *viz.* 16 feet. The ram weighed 15 cwt. and the piles usually drove in 5 blows one inch; sometimes, however, they required 20 blows for the inch.

In some instances, when the pile-heads broke from defects in the castings, a cast-iron dolly or cap was used, 2 inches thick, to receive the blows of the monkey.

The only difficulty experienced in driving them, to retain them at their proper lines, arose from irregularities in the casting; it often happened that piles came an inch hollow in their face, and sometimes as much rounding; of course it could not be expected that piles, which could not fit previous to their being driven, would be any better after driving; further, from their crookedness, as must be known to all experienced in pile driving, it is almost impossible to drive them as they are pitched, as the blow of the monkey cannot be kept in the centre of the pile; the straight piles kept their direction with great accuracy, unless when they were encountered by soil of unusual hardness, or by wooden piles and stumps in the ground.

Five of the piles only were broken from hard driving; the rest of the casualties were all from manifest defects in the castings, such as air holes, defect of metal in sectional area, imperfect connection of the metal when the different runnings met in the mould by cooling too quickly; it was fortunate that it proved so, for the difficulty in drawing the piles partly driven was very great. Bolts, 2 inches diameter, of the best iron, were frequently broken at close bearings by the strain, and in two instances, after a strain of upwards of 80 tons was tried in vain, the piles were obliged to be made good by splicing the top piece to the lower.

As the wharf curves sharply at each end, a difficulty presented itself from the toes of the piles having to spread more than the head, as they described a longer circumference from the batter of the wharf; this of course had to be overcome by piles of a parallel width, but was not effected without much difficulty.

Nevertheless, from the scale of the application of iron in this instance, *viz.*, 750 feet long, 33 feet high, and

Mechanical Processes.

Manufac-
tures.

from the nature of the soil driven through, the practicability of its application to river walls, &c. is clearly proved.

Yet more care is certainly required from the people in pitching and driving these piles than wooden piles, as no adjustment can be obtained, when any irregularities occur, by altering the form and shape of the pile to suit any particular purpose. The castings were executed principally at the Butley Company's Iron Works, near Newcastle-on-Tyne, and the very few fractures which occurred, after they became aware of the nature of the Work, is very creditable to that establishment. Some of the piles were also supplied from the Horsley Company's Works, Staffordshire.

Pl. lv.
Fig. 1.

Fig. 1 is a section of the wharf, *a b* is the front of the old wharf; *c d* is what is called a needle, driven in every seven feet for the purpose of receiving the ties which secure the iron pile, which is itself tied back by a land tie to a wall on the old timbers, as shown in the section; *e f* is a wooden guide pile, one of which is driven every 14 feet, carrying the wales *g g*, which serve for direction in driving the iron piles, and also for bolting thereto the sheet piling. Fig. 3, *k k*, is a mass of concrete filled in, and forming the back to the iron piling, 22 feet deep, 9 feet broad at bottom, and 5 feet 4 inches at top, by which the back is perpendicular to the horizon.

Fig. 3.

Fig. 2 is a front elevation of the wharf. The main piles are in two lengths, their joining parts being marked *a a*, &c. The section of the upper length is represented in fig. 3, at *l*, and of the bottom length at *m*, and the plan of the point of joining at *n*; the square hole in the bottom pile for receiving the spigot of the upper pile is shown also in the figure, and *h* is a hole through each flanch for receiving a $1\frac{1}{2}$ inch bolt for additional security. The sheet piling is shown at *b b*, &c., but its figure will be better understood by the section, fig. 3, where *r* represents a rib for covering and receiving the abutting end of the next pile; this is, of course, only required at one end, the other *r* being received behind the flanch on the main pile; *d d d*, &c. represent the plates for filling the space between the main piles above the sheet piling, the section and method of securing which is shown by *s s*, fig. 3, one of these flanches being on each plate, and are bolted together through the holes seen in the plan.

The plate in fig. 2 is what is called the mooring plate; this is cast concave to receive a mooring ring, which, by this means, does not project beyond the face of the wharf.

Patent ce-
ment
wharfs.

(861.) *Patent stone or cement wharf*.—A wharf wall of this kind has been formed 270 feet in length, at the East end of His Majesty's dock-yard, Woolwich. The operation was commenced by driving a few piles, which are intended to be left as defences to the wall, as in the usual stone wharfs; against these pilings planks were temporarily nailed, the back of which corresponded with the intended face of the wall, and behind these was thrown in the cement, mixed as hereafter described, which almost immediately set and became converted into an artificial stone, and being formed to represent stonework can scarcely be distinguished from a real stone wall; any given length being thus finished, the planks are removed, put up in another part, till this is also finished, and so on till the Work is completed. At certain intervals, instead of the stone cement thus formed, layers of artificial blocks of the same material are intro-

duced, of which also school-houses, churches, &c. have been built. These artificial stone blocks are formed by casting the cement into wooden boxes made to the required size and shape, and which when removed differ very little in appearance from actual stone. As, however, it would be improper to trust too much to their tenacity, the common mode of lifting and lowering by the *lewis** is avoided, and holes are formed through them by an iron pin fixed in the mould or box, by means of which, or by slings, the stones may be lifted, lowered, and adjusted.

In order to obtain the best information relative to this novel practice, the writer applied to G. L. Taylor, Esq. the Admiralty architect, under whom the Work above described was constructed, and some other important applications of the patent cement had been made, and he has obligingly furnished the following sketch.

"The patent stone or concrete is composed of clean gravel and sharp sand, and *lime* of the best quality ground to an impalpable powder; by using it *fresh* with *hot* water the utmost strength is obtained, and it sets immediately; enclosed in boxes of any shape, by working up the face which is to appear, ashlar or mouldings are formed exactly resembling stone, and, if properly done, possessing the qualities thereof. The proportion of lime to gravel depends on the quality of the lime, and in that and the method of mixing and using them, in which much judgment and attention are requisite, depends the quality of the material. It is applicable to house-building, and possesses the advantage of having both the exterior and interior of the walls finished as the Work proceeds, leaving only ceilings to dry, and the building may be made to possess an architectural character at less cost than the plainest brick one. I have erected a school at Lee, a fac-simile of the Propylæa at Athens, with this result.

"At Chatham, I caused a new foundation to be put under the whole of the walls of a storehouse 540 feet in length, in four months. The building had been erected about 40 years on timber sleepers and plank which had decayed; we had to excavate on each side of the walls to a depth of from 16 to 26 feet, to take out the decayed timbers, from 2 to 6 feet in height, and 6 to 7 feet in width. The concrete was put in in a liquid mass to within a foot of the bottom of the old walls, when a large slate was bedded, and that foot was *pressed* in by an iron frame with 2 strong screws on each side of the wall, in lengths of 4 feet, and the weight of the superincumbent wall, 50 feet high, 5 feet thick, was taken on the material the next day without the least subsidence.

"In another building at Chatham, which had settled, we raised the part up bodily 3 inches by the same method. At Chatham we are also constructing a dock of

* It may be proper for the sake of some of our readers to describe this very ingenious apparatus, which is represented in fig. 4, plate lv. It is used in lifting large blocks of stone. A hole is cut in the upper face to the depth of 3 or 4 inches, widest at bottom. There are three pieces of iron with a hole through each to receive the pin of the tackle *s*. The pin being withdrawn, the two side pieces are dropped in the hole, and their wedge-formed sides brought to the sides of the hole. The straight centre piece is then dropped in and the pin inserted. Now, the tackle being applied to the hook, the weight of the stone presses the wedges against the sides of the hole, and the block is borne up with safety, although always to the terror of the inexperienced looker-on.

Manufactures.

this material, the sides are done in mass, the bottom is laid as masonry in large blocks cast in boxes, and all lined with granite. The expense of this dock is barely a tenth of the amount they have usually cost.

"At Woolwich we constructed, a year ago, a river wall 270 feet long, 26 feet high, 7 feet broad at bottom, 4 feet at top. This was done without any protection, the river flowing on it every tide; we commenced by putting in the material behind boards, but latterly adopted the plan of forming the face with blocks cast in boxes set in masonry and backed with the material in mass. At Woolwich also a dock is constructing of the same material. The springs being very strong have occasioned several experiments to be made; we have now overcome them by adopting the method of setting the bottom with two layers of cast material as masonry, by which means the running water does not extract the lime as it does when the material is in a liquid state.

"The foregoing is the experience I have had of this material; for any further information I must refer you to the patentee, Mr. Ranger, Stangate, who had applied it to buildings before I knew him, but the application to river walls, docks, and undersetting were of my adoption."

MECHANICAL PROCESSES AND MANUFACTURES.

This head includes a very great variety of operations; indeed, nearly every mechanical Art might be given under so comprehensive a title; but we propose to confine it only to those which belong to the manufacture of articles formed of metal or fibrous substances: such as do not fall under one or other of these divisions, will be given under the head Miscellaneous Mechanical Arts.

Mechanical Processes in Metals.

Button-making.

Button-making.

(862.) To follow out strictly the arrangement above stated, we should have to treat here only of the manufacture of metal buttons; whereas buttons are made of a great variety of substances. In most of them, however, metal is employed to form the shank; and even such as have no metal in them we shall give under the present Article.

The different kinds of buttons are very numerous, being formed of the following substances; *i. e.* metal buttons, including steel, copper, plated, or gilded, white metal, gold, silver, &c., glass, stone, mother of pearl, ivory, horn, bone, tortoiseshell, paper, and leather. Many other substances are also manufactured into buttons; besides moulds of different kinds, which are afterwards covered by silk, mohair, horse-hair, &c. It will, of course, be impossible for us to enter minutely into a description of all these processes; we propose, therefore, to confine our principal description to those made in greater numbers, and in which Machinery is more generally had recourse to.

Gilt buttons: cutting the blanks.

Gilt buttons.—These are formed of copper, with a little alloy of zinc. The metal is first taken to a rolling-mill, and reduced to the proper thickness for the button, and its edges properly squared off with shears. The rolling-mill and shears employed for this purpose differ only in size from the Machines described under Shears (Art. 449.) and Rolling Mill, (Art. 541.) and are commonly worked by hand; these, therefore, require no particular description.

VOL. VIII.

The copper thus prepared is brought to the button manufactory, and cut out into blanks of the intended size of the button by means of a small fly-press. This work is commonly performed by women or boys, who acquire a dexterity in the operation which is truly astonishing to a stranger. Taking the sheet of copper in one hand, the other being free to urge the flyer of the press, the copper-plate is pushed forward, and the blanks successively cut out, both in the length and breadth of the plates, till the part remaining is a complete skeleton, the circular holes being separated from each other only by mere lines of metals.

(863.) *The fly-press* varies considerably in its form, and appears to have received its denomination from being commonly worked with a fly; but in the manufacture of buttons it retains only the name of the fly-press, being worked by means of a lever only, unless, indeed, the slightly weighted handle can be considered any apology for the denomination; in other respects, however, the Machine is the same. Fig. 1, 2, &c., plate lvii., is the representation of a very usual form of fly-press, as employed by button-makers, and for other purposes. The frame is cast-iron; in the upper part of this frame is a screw box fitted, and the screw B passing through it. The top of the screw is fixed to a curved handle *a b c*, furnished with a weight *c*, which acts as a fly when the handle is turned round by a boy or woman sitting before a bench or table, on which the press is fastened by two bolts passing through projecting pieces D D of the iron frame. At *e* a piece of iron is fastened, projecting from the iron frame, and supporting a socket for the square iron slider *f* to slide up and down, and to avoid any shake in its motion. The socket can be at any time made to fit the slider by the four screws seen in the side, fig. 3, which draws the two halves of the socket together. The upper end of the slider *f* is connected with the screw B, by a joint which allows the screw to turn round independently of the slider, but obliges the latter to accompany the screw in its vertical motion, either ascending or descending. At the lower end of the slider *f* the punch or tool *g* is fastened by a clamp screw; it acts in combination with another tool *h*, called the die, fixed below it in the frame by four screws *i*, (shown in fig. 3,) which allows of its adjustment in the true position beneath the tool. The lower tool or die is fitted into a block which is held by four screws; and by this means the die can be quickly changed without disturbing the press. The upper tool can be removed in the same manner, by releasing the clamp screw, which holds it in the slider *f*. These are the essential parts of any fly-press; but, generally, for the purpose of the button-maker, they are less massive than is here described, although, in principle, there is no difference. With respect to form there is great variety; that above described may be considered the most simple. The operator (which is, as above stated, generally a woman or a child, where the object is only to cut the blanks for buttons) is seated on stands before the press, holding the plate of copper in the left hand over the lower hole, while he draws the handle towards him with the other, which turns the screw, urges the punch down upon the metal, and forces out the blanks as above described, which fall into a drawer below, placed there to receive them.

(864.) The next step, or at least the collateral step with cutting the blank, is that of forming the shank, which is made of either brass or iron wire. The old method of

Mechanical Processes.

Plate lvii.
Fig. 1, 2, 3.

Forming the shanks.

Manufac-
tures.

Plate lvii.

7.

Fixing on
the shanks.

Dipping.

Gilding.

effecting this was to fix in a lathe a steel bar of a form in its section resembling fig. 4; this bar being close, covered with successive spires of the wire, as in fig. 5, is removed from the lathe: a long staple-shaped wire (fig. 6) is then introduced, and by means of a long punch or cold chisel a blow is struck along one side, giving to each fold the form shown in fig. 7, and the whole being now cut up the middle, every spire of the spiral is converted into two complete shanks. Such was the usual method of forming the shanks, and it is still very commonly adopted; but frequently now the shanks are formed by a very ingenious little Machine of recent invention, which works by the continuous motion of a winch. Here the wire, of which the shank is made, is brought from a reel to the Machine; and, one end of the same being introduced, the engine draws it in, cuts it to its proper length, and then the two ends are pressed up over a steel pin of the proper size; and a small hammer immediately strikes the ends of the shank a few blows, which flattens them, and facilitates the subsequent soldering; the shank is then slipped off the pin, and another length of wire cut, and so on without intermission; the whole being performed by a woman or boy turning a handle, no skill whatever being required in the operator.

The shanks thus formed are secured to the bottom of the buttons by a small iron or wire clasp, somewhat resembling a pair of tweezers, and a small quantity of solder and resin applied to each. They are then placed on a sheet of iron containing about a gross, and introduced into a very hot stove, where they remain till the workman is satisfied that the solder has melted, and that the shanks are united to the button, after which the edges are smoothed in a lathe.

The next process is what is called *dipping*; that is, a number, consisting of a few dozens, are put into an earthen vessel full of small holes like a colander, and thus dipped into dilute nitric acid to clean them from dirt and rust. They then, according to the best practice, go into the hands of the burnisher, who, in a lathe, burnishes the tops, buttons, and edges with a hard, black stone, got from Derbyshire, secured in a handle like the diamond of a glazier: this he applies to the button fixed in the end of a piece of wood, turned with great velocity by means of a treadle, with which he works the lathe. This is called *rough burnishing*, and is a modern improvement: it is of great advantage, by closing the pores of the metal opened by the acid, so that the gold afterwards to be applied attaches to a smooth surface, which, otherwise, might enter into imperceptible cavities, and be closed up in the body of the button by the final burnishing. When the buttons come from the burnisher they are fit for gilding. This is a very curious operation, and wholly chemical.

(865.) The first process towards gilding is what is called *quicking*, which is effected as follows:—Any number of buttons, perhaps a gross, is put into an earthen vessel with a quantity of mercury, which has been previously saturated with nitric acid; and thus the buttons and mercury are stirred together with a brush till the mercury adheres to the whole surface of the button. These are then taken out and put into what is called a *basket*, though, in fact, an earthen vessel full of small holes, the handle of which the operator holds in his hand, and jerks it with considerable force down towards a wooden trough, (a receptacle for the quicksilver,) till, by repeated jerks, all the loose particles of mercury

are disengaged, leaving a complete continuity over the surface, and giving them the appearance of silver buttons.

The gold, a grain of which will spread over many superficial feet of copper, is thus prepared:—Any given quantity of mercury is poured into an iron ladle, the inside of which has been previously *guarded*, that is rubbed over with dry whiting to prevent the gold from adhering to the iron: into this mercury is thrown the portion of pure gold intended to cover a certain number of buttons. The gold and mercury are heated together in the iron ladle till the workman (whose practice soon enables him to judge) perceives there is a perfect union between them, when he empties his ladle into a vessel containing cold water.

The amalgam being cold is put into a piece of shammy leather, and squeezed till no more mercury will pass through. What passes the shammy contains not the smallest portion of gold; and what remains will be about the consistency of butter, so completely united that every particle of mercury shall contain an equal portion of gold. The amalgam should be then put into an earthen vessel, and a small quantity of nitric acid added, allowing sufficient time for the acid to unite with the mercury. But the buttons and amalgam are commonly introduced first, and a quantity of dilute nitric acid added thereto, so that, for want of a complete union between the mercury and first acid, if there be not a superabundance of acid, there may not be sufficient to carry all the amalgam to the surface of the buttons.

When the acid has had sufficient time to *embrace* (as workmen call it) the mercury, the buttons are introduced, and stirred till the amalgam, carried by the affinity of the acid to the copper, and the tendency which the gold has to extend itself to the mercury with which the buttons have been previously quickened, completely attaches to the whole surface.

The gilding being thus far completed, the next thing is to recover, for subsequent operations, the mercury which has been employed; and the following method is recommended by the author of the above description, *Philosophical Magazine*, vol. ix.

The old practice was, after the buttons had been completely covered with mercury and gold, for the operator to proceed to what was called *drying off*, which was performed thus:—The buttons, to the amount of a few dozens, were put into an iron pan somewhat like a large frying-pan, placed over a fire, and gently shaken, while the operator watched carefully till he observed the mercury begin to flow; upon the first symptoms of which, he took the pan from the fire, and threw the buttons into a large cap, called a *gilding cap*, like a man's hat with a very small brim, but much larger in the crown, made of coarse wool and goat's hair. In this cap, with a circular brush, the buttons were stirred, to spread the gold and mercury while in a degree of temperature nearly sufficient to volatilize the mercury. The buttons were thus again thrown into the pan, placed over the fire, and shaken, while the mercury gently volatilized, when the buttons were again thrown into the cap and stirred with the brush. This process was continually repeated, till all the mercury was volatilized, leaving the gold on the buttons, which appeared again of a yellow colour. By these means the principal part of the mercury ascended the chimney and was deposited on the tops of the houses and about the adjacent neighbourhood, and great quantities were inhaled and

Mechanical
Processes.

Drying off
by the old
method.

Manufac-
tures.

absorbed by the operator, keeping him nearly in a state of salivation, till disease obliged him to desist. Every one who has formerly visited our button-manufactories at Birmingham, and elsewhere, can bear testimony to the emaciated state of the parties, mostly women, employed in this unhealthy process.

Considerable quantities of mercury thus volatilized are found united and collected in small pools in the spouts and gutters on the tops of the buildings. Thus many tons of mercury have been dissipated about the town and neighbourhood, to the great injury of the inhabitants. The poor sweep who has ascended the chimneys has been salivated, and the manufacturer has sustained considerable loss.

New pro-
cess re-
commended.

To preserve a principal part of the mercury thus dissipated, and to prevent, in a great measure, the terrible effects of it on the constitution of the operator, the following process has been recommended by the author above referred to.

Plate lvii.
Fig. 8.

By means of an apparatus similar to the plan delineated in fig. 8, which was first partially and successfully adopted by Mr. Mark Sanders, an eminent button-maker of Birmingham, the principal part of the mercury may be recovered, and the health of the operator greatly preserved.

A hearth of the usual height is to be erected, in the middle of which a capacity for the fire is to be made; but instead of permitting the smoke to ascend into the top of it, made of sheet or cast iron, through which the mercury is volatilized, a flue for that purpose should be conducted backwards to the chimney B. An iron plate, thick enough to contain heat sufficient to volatilize the mercury, is to cover the fire-place at the top of the hearth C. There must be an ash-hole D under the fire-place. The square space E, seen in the fire-place, is the flue which serves to carry the smoke back under the hearth into the chimney B. The door of the fire-place and ash-pit may either be in front, as represented in the plate, or at the end of the hearth at F, which will perhaps less incommode the work-people. It would be of great advantage if the space between it and the iron plate C was covered up with a glass window coming down so low as only to leave sufficient room for moving the pan backwards and forwards with facility. If the sides are also glass instead of brickwork, it would be still better, as the work-people would be able to have a full view of their work without being exposed to the fumes of the mercury, which, when volatilized by heat communicated to the pan by the heated iron plate over the fire-place, would ascend into the top A, appropriated for its reception, and descend into the tub G', covered at top and filled pretty high with water. By this means the hearth would, in fact, become a distilling apparatus for condensing and recovering the volatilized mercury. In the tub G', the principal part would be recovered; for, of what may still pass on, a part would be condensed in ascending the tube H, and fall back, while the remainder would be effectually caught in the tub or cask I, open at the top and partly filled with water. The latter tub should be on the outside of the building, and the descending branch of the tube H should go down into it at least 18 inches, but not into the water. The chimney or the ash-pit should be furnished with a damper to regulate the heat of the fire. The water may be occasionally drawn out of the tubs by a siphon, and the mercury, clogged with heterogeneous matter, may be triturated in a piece of flannel till it passes through, or placed in a pan of sheet iron, like a dripping-pan, in a

sufficient degree of heat, giving it a tolerable inclination, so that the mercury, as it gets warm, may run down and unite in the lower part of the pan. But the mercury will be most effectually recovered by exposing the residuum left in the flannel bag to distillation in a retort made of iron or of earthenware.

Mechanical
Processes.

When the mercury is volatilized from the buttons, or, as the workmen denominate it, when the buttons are dried off, they are finally burnished, and are then finished and fit for carding.

The reader unacquainted with this branch of manufacture will be surprised to learn how far a small quantity of gold, incorporated with mercury, will spread over a smooth surface of copper. Five grains, worth one shilling and three-pence, spread on the top of a gross, that is, 144 buttons, each of one inch diameter, are sufficient to excuse the manufacturer from the penalty inflicted by an Act of Parliament; yet many, upon an assay, are found to be deficient of this small quantity, and the maker fined and the buttons forfeited accordingly. Many hundred grosses have been tolerably gilt with half that quantity; in which case the thickness of gold is only $\frac{1}{214000}$ th of an inch; so extremely far can gold be spread, when incorporated with mercury, over the surface of a smooth piece of copper.

(866.) *Plated buttons.*—These are stamped by the fly-press, as above described, but are cut out of copper plated with silver on one side, rolled at the flattening-mill. The copper side is placed uppermost in stamping, and the die or mould, through which they are stamped, is chamfered at its edge to make the silver turn over the edge of the button. The backs are stamped in the same way as the gilt buttons, but the shanks are soldered on with silver solder, and heated one by one in the flame of a lamp or gas-light with a blow-pipe urged by a pair of bellows. The edges are then filed round in a lathe, care being taken not to remove any of the silver which is turned over the edge. They are next dipped in acid to clean the backs, and boiled in cream of tartar and silver to whiten the backs, after which they are burnished, the backs being first made clean by a brush held against them as they revolve in the lathe. The burnishing is performed exactly as that of gilt buttons above described.

Plated
buttons.

Cup or convex buttons, either plated or gilt, are made of two pieces, viz. a common flat button with a shank and a small hemisphere fixed on in front. These hemispheres are punched out by the fly-press, and then the inside is turned in a chuck lathe to receive the edge of the plain button made as before described; when put in its place the edge of the cup is burnished down over it to hold it fast. These buttons are afterwards gilt and burnished like the plain ones as above described. But tons with a hoop or projecting ring round their edges are made in the same way.

Cup but-
tons.

White metal buttons are formed of a common white metal, a compound of brass, pewter, &c. The metal is not here rolled into plates, as described in the last Article, but is cast into moulds in which the shank of iron wire is previously placed. The mould is formed by a metal pattern, consisting of a great number of circular buttons, connected by small bars from one to the next to form a passage for the melted metal. An impression from this pattern, which frequently contains as many as twelve dozen buttons, is taken in the sand in the usual manner, and the shank is pressed into the sand in the centre of each impression, the part which is to enter the metal being left projecting above the surface of the sand.

White
metal
buttons.

Manufac-
tures.

The metal is now melted and cast into the mould, a little zinc being commonly added to cause it to flow more freely, thereby to fill the mould more completely, and to produce a sharp casting. The buttons, being thus cast and taken from the mould, are cleaned from the sand by brushing; they are then separated from each other by breaking the small metallic bars which unite them, and taken to another workman at a lathe, who inserts the shank of each button into a chuck of a proper figure, in which it is retained by the back centre of the lathe being pressed against the button with a spring. Here the circumference is reduced to a proper circle, and the button is instantly released by the workman pulling back the spring, and another button is introduced. A third workman turns the back of the button smooth in a chuck lathe, and makes the projecting part round the shank true, and a fourth workman renders the face of the button smooth by placing it in a chuck and applying the angle of a square bar of steel across its centre. As it is not thought necessary to make the surface of the button perfectly flat, the tool is only held in the hand, which greatly facilitates the operation, as by this means any small deviation from the truth is followed much more readily than the surface could be cut if the tool was fixed in a rest. The next operation is polishing the button. Here the shank is held in a piece of wood, and the face is rubbed on a piece of board covered with leather, and spread with powdered rotten-stone and oil, and afterwards with a finer powder. The last polish is now given by applying the button lightly to a flat surface of a circular board, covered with soft leather, turned by a lathe, and dressed with exceedingly fine powder of rotten-stone. These polishings are generally performed by women; and the buttons are now finished, except that they have still to be boiled to render them white. For this purpose melted tin is poured into cold water and by this means granulated. A quantity of cream of tartar diluted with water is put into a boiler and tin added to it, a part of which is dissolved by boiling, and the buttons being let down into it on a wire grating, part of the tin attaches itself to the surface of the buttons, whereby they are rendered white while they retain their former polish. In this state they are placed on a card for sale.

Different
description
of shanks.

(867) We have hitherto described the shanks as they are commonly formed, but different methods and forms have been proposed, of which the following is the most recent, as also by far the most simple. Here the disc or face may be of any of the substances usually employed in button-making, there being nothing peculiar but in the form of the shank; this part is made to project from the back of the button, it has no eye to be turned over and sewn to the cloth, but is made straight and of some thickness. It may be made out of the same piece of metal as the button, or it may be made separately and rivetted on to the back. The end of the shank is a small projection from the shank as the latter is from the button. To this last projection a washer is fitted, so that, instead of sewing on as usual, a hole is made in the clothes, the shank passed through, the washer is then applied, and with a small hammer the end of the shank is rivetted so as to overlap the end of the washer, and thereby to secure the button tightly in its place. It is, of course, exactly the same thing whether the rivet is placed inside or over the button, but, in the latter case, the rivet should be made ornamental. Other plans are suggested by the patentee, such as to make the shank of the washer a

tube, and the shank of the button a rod to fit it, &c. Mechanical Processes. It is considered that by this means of putting on the button it will fix tighter and the clothes fit better than according to the common method.

Other patents for buttons, shanks, &c., will be found in vols. xii., xiii., old series of the *Repertory of Arts*, and in several volumes of the second series. The patent above described is from vol. lix. of the same Work.

Hitherto the buttons have been described as plain gilt or plain plated, but the surface of both is sometimes ornamented with particular figures, concentric and eccentric circles, or portions of circles in every variety of combination. This is done sometimes in a lathe by applying a milling tool to the face; this tool is a small steel roller with the intended pattern engraved on its periphery, it is held in a simple slide rest which thus makes the circles on each successive button of the same size, and occupying the same part, to the number required, when the pattern may be changed by changing the tool.

Another way of ornamenting the face of buttons is by means of a small Machine furnished with wheel-work, so contrived that, a button being placed upon it and a handle turned, it is made to revolve either concentric or eccentric with the central wheel of the Machine. There is also a small hammer like a rivetting hammer pressed by a spring; this is successively lifted and forced down by the spring as the Machine is turned, and by the blow a small indentation is made on the button, either a point or line, and as by the structure of the Machine the button may be placed eccentric in any degree, an immense variety of patterns may be formed by the slightest change or adjustment of the parts.

(868.) *Glass buttons.*—These are frequently wholly composed of glass variously coloured, in imitation of opal, topaz, and other stones. The method of forming them is as follows: the glass is kept in a state of fusion, and the button nipped out of it, while in a plastic state, by a pair of iron moulds, like those used for casting pistol shot, adapted to the intended form of the button, the shank being previously inserted into the mould, so as to become imbedded in it when the glass is cold.

Mother of pearl buttons.—The disc of mother of pearl, being already formed to the proper size and thickness of the button, is drilled in the centre and slightly under-cut. The shank, then, formed as already described, being driven in with a steady stroke, its extremities extend on being driven against the bottom of the hole, and become thus firmly rivetted into the button. To this kind of button are frequently added fossil stones, usually attached to the surface by isinglass glue; steel studs are also sometimes rivetted into buttons of this and various other kinds.

Shell buttons are those which consist of a back made of bone without any shank but corded with catgut, and covered in front with a thin plate of metal struck with a die. The backs are cut out with a brace or stock, the bit of which is a sort of crown or trepanning saw, and the four holes through which the catgut passes are drilled according to the method described in the following article. The backs are then corded by children, who tie the catgut on the inside; the cavity is then filled with melted rosin and the metal shell applied warm. The button is then pressed between two centres in a lathe, described also in the following article, and being thus forced together the shell is burnished round the back during the revolution by a small burnisher. The

Manufactures.

Pl. lvii.
Fig. 9

method of punching out the concave shell of these kind of buttons is as follows: first, small circles are cut out from the plate in the manner already described for plain gilt buttons. This circle of metal being placed over a die of the proper form, shown in fig. 9, is forced through by the end of a tool or punch K, which being smooth and of a spherical figure causes the plate to assume the same form, which passing through the die into a drawer beneath is in a state fit for use; the aperture of the die L being exactly such as to admit the tool to pass encompassed by the thickness of metal. The upper side must not be left sharp, but rounded off so as not to cut, but simply to bend, the metal in passing through it; the circle of metal must also be larger than the hole, in order that it may rest over it, and be large enough to form the cup or spherical segment as shown at s in the figure.

Horn buttons.

(869.) *Horn buttons* are made either with or without shanks, the latter being commonly called sailors' buttons; in this case the surface of the button is concave, and four holes are pierced through the sunk part for sewing them upon the clothes, the thread being protected from the wearing to which it would be exposed but for the projecting edge of the button. These kind of buttons, although always known under the term horn, are, in fact, formed from cow-hoofs, by an ingenious process of pressing them into heated iron moulds. The hoofs are first prepared by being boiled in water till they become soft; they are then cut into parallel slips by a cutting-knife, which is a blade with a long handle at one end, and jointed to the bench by a hook and eye at the opposite extremity, after the manner of a patten-maker's tool, and which, as in that case, acts as a lever in cutting the horn placed beneath its edge. The slips being the width of the intended buttons are cross-cut into small squares, after which, the angles being taken off, they are reduced to an octangular shape nearly the size of the intended buttons. The next process is to dye them black, which is done by dipping them into a vessel of water impregnated with logwood and copperas. They are then left to dry for about a week, when they are in a proper state for pressing. This is performed as follows: two iron cheeks are provided, each having six, eight, or more small steel dies fixed to it, each die containing the intended impression of the button embossed on it; these plates or cheeks are connected by a long handle to each, which open and shut like a bullet-mould, and when shut the pairs of dies exactly correspond. The workman being provided with a sufficient number, nine, ten, or twelve, of the pairs of moulds, arranges them in an oven or furnace till they become heated somewhat above that of boiling water. A piece of horn cut as above described is then placed above each impression in the mould; this is now shut and held in close contact by being placed in a small screw-press upon the work-bench for a few minutes till the horn is heated and softened. The mould is then removed to a powerful screw-vice, which consists of two very heavy cheeks drawn together by a screw in the usual way, differing only in its size from the common vice, but placed somewhat otherwise, merely for convenience in bringing on the pressure. The mould with the horn in it being placed between the cheeks, and brought nearly central, is pressed so violently, by the combined power of the screw and lever, that the horn is indented with the exact patterns formed in the mould; it is then left to cool, which requires about twenty minutes, more or less, according to

circumstances. At all events the horn must remain in the mould till it is cold, as otherwise it would go from its figure when removed. Nine presses are generally arranged round the stove, which give constant occupation to one workman.

Mechanical Processes.

The buttons being removed, some edges are left which did not enter the dies; these are now clipped off by shears; the button is then placed in a lathe, and filed smooth and round. The method of performing this requires some explanation. The lathe in which the work is performed has two spindles; both are turned with the same velocity by straps from two equal foot-wheels on one axle; the ends of the two spindles come in contact, and have each a chuck with a cavity for the reception of the button. One of these spindles is pressed forward with a spring, and which thereby holds the button fast between the two while it is turned round and its edge filed smooth. This is very quickly done; the spring is then pressed back by a lever provided for the purpose, while the spindle is still in motion; the button immediately falls out into a box beneath; another button is put on, the spring again relieved, which, as before, brings the chucks together, and holds the button between them till it is in its turn relieved, and so on with very great rapidity.

We have in the above description supposed the operation to relate to sailors' buttons without shanks; the work is not, therefore, completed in the above process, it still remains to form the holes for the purpose of their being sewn on the clothes. These are made by means of a lathe having four spindles parallel to each other, and all turned by the same foot-wheel by means of two straps, each turning two spindles. These spindles, however, could not be brought sufficiently near to each other, in consequence of the pulleys upon them, to make the holes so close as they are required to be. Each of them has, therefore, a hook at the end, by which it is connected with another spindle, and these four are now made to incline towards each other so as to pass through an iron cheek or standard in which the four holes are brought to their proper distance, and their points, which project a little way through, are there formed into small drills. The buttons are now successively placed in a concave rest, and thrust against the drills by a piece of wood; the four holes are thus made in an instant, another button is then drilled, and so on. The spindle, having freedom by means of the hooks, may be brought to any distance; it is, therefore, only necessary to change the standard in order to change the distance of the holes according to the size or the intended pattern of the button. A little roughness is produced on the surface of the button by the drilling, which is removed by shaking a number of them together in a flannel bag.

At present we have not spoken of those horn buttons that are furnished with shanks. In these the shank is inserted before pressing by children, by drilling a hole to receive them; the mould also has a hole to receive the shank, and in the moulding, which is performed precisely as above described, the horn is so pressed against the shank as to secure it very effectually in its place.

Coining.

(870.) Before entering upon an explanation of the mechanical operation of coining it may be well to give a sketch of the history of the nature and value of the

Coining.

Manufac-
tures.

different kinds of coinage which have been at times in circulation in Great Britain, and of the relative value of the two principal metals, gold and silver, at different periods.

Usual alloy.

Gold and silver, in their pure state, are too soft and flexible to be formed into coins; they must therefore be alloyed with some other metal or metals, and in this Country they are both alloyed with copper, silver, &c., in the following proportions *viz.*, pure gold 22 + 2 copper = 24, the alloyed metal being supposed to be divided into twenty-four parts, called carats; and it is said to be twenty-two carats fine, that is, of twenty-four parts the pure gold is to form twenty-two. The alloy of silver consists of thirty-seven parts of pure silver and three of copper, and its fineness may therefore be expressed by the fractions $\frac{37}{40}$. This proportion for the alloy of silver coin, which was at the time the only standard, was first fixed in this Country in the time of Richard I. by certain persons from the Eastern parts of Germany, called Easterlings, and hence, by contraction, is said to have arisen our word sterling, to imply of proper standard value: it was also the name originally given to the silver penny.

Experi-
ments to de-
termine the
best alloy
for coin.

(871.) The alloy used in standard gold having been fixed long before that precision was introduced into the Arts which has place at present, it became a question with the British Government, about the commencement of the present century, whether the above proportion was the best that could be devised for preventing the wear and gradual depreciation of weight which our gold coin was known to be subject to; and accordingly a Commission was appointed to inquire into various questions relating to the hardness, ductility, specific gravity, and other circumstances requisite for determining the best alloy for the purpose of coinage. This Commission called to their aid the able assistance of the Honourable Mr. Cavendish and Mr. Hatchett; and the latter, in 1803, gave in the *Philosophical Transactions* an interesting account of the experiments which had been instituted in order to enable him and Mr. Cavendish to make their report. Alloys were made of gold with thirteen different metals, but it appeared from them that, agreeably to general practice and opinion, only two of them are proper for the alloys of gold coin, namely, silver and copper, as all the others either considerably alter the colour, or diminish the ductility of the alloy. In respect to the latter quality the metallic substances that were employed appeared to affect the gold in nearly the following decreasing order:

- | | |
|---------------|-------------------------------------|
| 1. Bismuth. | } These are nearly equal in effect. |
| 2. Lead. | |
| 3. Antimony. | |
| 4. Arsenic. | |
| 5. Zinc. | |
| 6. Cobalt. | |
| 7. Manganese. | |
| 8. Nickel. | |
| 9. Tin. | |

| 12. Copper. | |
| 13. Silver. | |

Specific
gravity of
different
alloys.

The next subject examined was the specific gravity of different alloys, from which was obtained a long series of results, which we cannot of course give in this place; but the three following on standard gold are important: at the same time Mr. Hatchett admits the extreme diffi-

culty of obtaining perfectly accurate results, in consequence of the unequal union of the different metals in the melted metals. The numbers he has given are, however, as follows:

Gold made standard by silver	17.927
Gold made standard by silver and copper	17.344
Gold made standard by copper	17.157

And it is remarked, that as our gold coin commonly contains silver as part of the alloy, and as at different times this proportion of silver must have been various, particularly when the gold of Portugal, which is alloyed with silver, was brought to the Mint, it naturally follows that, exclusively of any other causes, the specific gravity of our standard gold must occasionally be different according to the relative proportions of silver and copper which compose the alloy; moreover, an exact distribution of the alloy is not very easily made where a large quantity of gold is to be alloyed.

In the regulation of the Mint these discrepancies have been considered, and an allowance has been made for it, which is called the *Remedy for the Master of the Mint*, according to which, when the trial of the *Pix*,* as it is called, takes place before the Lord Chancellor, the Lords Commissioners of the Treasury, &c., for inspecting the standard value of the coinage, the Master of the Mint is held excusable if the imperfection or deficiency of the coin in the aggregate is less than a sixth part of a carat, equal to forty grains, of fine gold in the pound, or the hundred and thirty-second part of the value.

The next experiments were made on the comparative wear of different alloys, both on plain pieces and those with raised figures, milled edges, &c.; and with a view to these a machine, suggested by Mr. Cavendish, was constructed, so as to expose the pieces to different degrees of friction; but here again it was found that the present alloy of our standard coin was amongst the best that could be suggested to prevent that wear which had been observed, or rather which was assumed, to be the cause of the depreciated weight; for the reporter seems decidedly of opinion that the diminution complained of is not the result of fair wear. The paper concludes as follows:—"Upon a comparison of the different qualities of the three kinds of standard gold which have been mentioned (*i. e.* gold with silver, gold with silver and copper, and gold with copper) it appears, strictly speaking, that gold made standard by silver and copper is rather to be preferred for coin; but, as gold made standard by copper alone is not very much inferior in its general properties, it may be questioned whether the few advantages which are thus gained will compensate the additional expense of the silver required for half the alloy; and, indeed, any extraordinary addition of silver appears to be the less necessary, as there is commonly some silver in the gold which is sent to the Mint, which, being reckoned as part of the alloy, contributes to produce those beneficial effects which result when silver is purposely added.

"From a general view of the present experiments

* The *Pix*, in the language of the Mint, is a box in which a small proportion or sample of the coins struck at the Mint is reserved, in order to be assayed and compared with a check piece or standard coin kept in the Exchequer for the occasion. This operation, which is called the *Trial of the Pix*, is performed with great ceremony, and with much exactness, in the presence of the Privy Council, the officers of the Mint, and a jury of the Goldsmiths' Company. It is said there is no instance on record in which the coin thus tried have been found to vary from the full standard.

Mechanical
Processes.

Remedy of
the Mint.

Wear of the
coin.

Manu-
tures.

there does not appear to be any very great or remarkable difference in the comparative wear of the three kinds of standard gold, all of which suffer abrasion slowly, and with much difficulty, and (as it has been already observed) the difference of wear between the two last mentioned is certainly but inconsiderable. For these reasons, and from the consideration of every other circumstance, it must be evident that the extraordinary loss which the gold coin of this Kingdom is stated to have sustained within a certain limited time, cannot, with even a shadow of probability, be attributed to any important defect in the composition or quality of the standard gold; and all that can be said upon this subject is, that some portion of this loss may have been caused by the rough impression and milled edge now in use, by which each piece of coin acts and is acted upon by the others in the manner of a file.

"The loss thus occasioned cannot, however, be considerable; for the quality of the present standard gold is certainly that which is well adapted to resist abrasion, especially in the case of the friction of coin; and this is strongly corroborated by the observation of bankers and others, who are in the habit of sending or receiving large quantities of gold coin from any considerable distance. When a number of guineas, rather loosely packed, have been long shaken together, by the motion of a coach or other carriage, the effects of friction are observed chiefly to fall upon only a few of the pieces. But it is not a little remarkable that although these are often reduced nearly or quite to the state of plain pieces of metal or blanks, yet, upon being weighed, they are found to have sustained little or no loss; and from this it appears that the impressions have been obliterated, not by any actual abrasion of the metal, but by the depression of the prominent parts, which have been forced into the mass, and become reduced to a level with the ground of the coin. Pieces of hard gold would not so easily suffer by depression; but the real loss would probably be greater, they being, in the case of the friction of coin against coin of similar quality, more susceptible of abrasion.

"Upon the whole there is every reason to believe that our gold coin suffers but little by friction against itself; and the chief cause of natural and fair wear probably arises from extraneous and gritty particles, to the action of which the pieces may occasionally be exposed in the course of circulation. But still it must be repeated that the united effects of every species of friction to which they may be subjected, *fairly and unavoidably*, during circulation, cannot produce any other wear than that which is extremely gradual and slow, and such as will by no means account for the great and rapid diminution which has been observed in the gold coin of this Country."

As the general results of each part of this inquiry have been noticed at the close of the different sections, a regular recapitulation would be superfluous. We may, however, observe that the experiments on the various alloys of standard gold concur with established practice and opinion to prove that only two of the metals, *viz.*, silver and copper, are proper to be employed in the reduction of fine gold to standard for the purpose of coin; but, at the same time, it must be allowed that the phenomena exhibited by arsenic, antimony, zinc, cobalt, nickel, manganese, bismuth, lead, tin, iron, and platina, are in many respects remarkable, and demonstrate the utility of a regular experimental investigation of metallic alloys.

Mechanical
Processes.

The contents of the second section show that numerous causes influence the specific gravity of metals; and amongst these it has been long ago observed that some metals, when added to others, generally produce contraction in the bulk of the mass, or an increase of specific gravity, but that other metals produce effects which are precisely the reverse. This, to a certain extent, is unquestionably true; but it does not follow that each metal which produces contraction or expansion, when added to others, should (as some have supposed) constantly produce similar effects, corresponding to the relative proportion of that particular metal; for we well know that some metals, in like manner, promote the fusibility of others in a much greater degree than could be expected from their natural or inherent fusible property; but then the maximum of this effect is produced by certain proportions of the different metals, and suffers diminution by any variation in these proportions. It appears, therefore, that this great degree of fusibility is a property peculiar to the compound, which cannot immediately be attributed to either of the component metals; and we are much deceived if those alterations in specific gravity, which, in like manner, are observed in the various metallic compounds, will not admit of a similar explanation; for, in respect to the contraction or expansion which takes place in consequence of combination, we may believe that there is a maximum of this contraction or expansion dependent on a certain relative proportion of the different metals.

The experiments on the comparative wear of gold, which are described in the last section, were attended with considerable difficulties; for this reason the conclusions have been founded only upon such facts as were uniformly the same under every circumstance. These general conclusions have been already fully stated; but we may again observe that gold of moderate ductility is (all things being considered) the best adapted to the purpose of coin, and that the real wear of such coin is, in all probability, very slowly effected; so that a long period of time must elapse before any considerable diminution in weight can be perceived.

The experiments contained in these three sections were limited to standard gold; and, allowing that some curious and instructive facts have been discovered, still more might have been expected from an extension of such experiments to gold variously alloyed in every possible proportion. But an immense addition to Metallurgical Science would, in all probability, be derived from a comparative investigation of the whole of the known metallic substances, formed into binary, ternary, and such like combinations, proceeding from the most simple to the most complicated, and accompanied by accurate observations on the lustre, colour, ductility, hardness, specific gravity, and fusibility of the compounds.

Our actual knowledge of the properties of metallic mixture is certainly very imperfect, and has by no means kept pace with the rapid progress of modern Chemistry. Few additions have been made to the compound metals employed by the Ancients: the various mixtures of gold and silver called *electrum*, those of the Corinthian metal, the varieties of bronze, the compound of copper and zinc, now called brass, the metal for specula, the metal called *argentarium*, (in some measure answering to our pewter,) the art of plating and of turning, and the process of amalgamation, evince how great a progress had been made by the Ancients in the mixing and working of metals.

Manufac-
tures.

Much, however, remains to be done, and much may be expected from a regular and systematical series of experiments on the properties of compound metals. For, exclusively of the immediate application of many of the alloys to economical purposes, it cannot be doubted that Science will derive other considerable advantages; our ideas concerning the properties of the metals, whether simple or mixed, will be much enlarged; and clouds of errors, with the traditionary prejudices which as yet shade this branch of human knowledge, will be dispersed.

Coinage in
England.

(872.) The first English gold coin of which there is any account was struck in the year 1257, by order of Henry III. It was of pure gold, weighing two pence or two sterlings of silver, and was to pass for twenty pence, whereby the relative value of gold and silver was as ten to one. The weight of this piece was about the third part of our present sovereign.

The next gold coinage was in the year 1344, when the gold *florin* was struck, which took its name from Florence, where it had been first coined in 1252. In German it was called a *gulden*, and in Holland a *guilder*, indicative in both cases of its quality; although the present guilder or florin is a silver coin.

Relative
value of
gold and
silver

The guinea, now supplanted by the gold pound or sovereign, when first coined, passed for about twenty shillings, but its relative value to that of silver was not fixed, so that it varied in value from twenty to twenty-one shillings, but was in the reign of Charles II. fixed in its value in comparison with silver, and from that time it always passed for twenty-one shillings, which made the relative value of gold and silver as $15\frac{1}{2}$ to 1,

which it still maintains, whereas we have seen that, when gold was introduced into this Country as money, the relative value of the two metals was assumed to be as 10 to 1. This relative value has, however, varied very considerably in different ages in nearly all Countries. According to Herodotus the relative value of the two in Persia was as 13 to 1
In Greece ancient historians state it as 12 to 1
In the time of Alexander the Great it was 10 to 1
In Rome, to the time of Julius Cæsar 10 to 1
but it afterwards was reduced to $7\frac{1}{2}$ to 1

Mechanical
Processes.

In England, up to the time of the discovery of America, it was as 11 to 1
..... 10 to 1
..... 9 to 1

In Spain and Portugal, in the time of Sir Isaac Newton 16 to 1

Other parts of Europe 15 to 1
And the last proportion, with very little variation, is still maintained in most parts of the Continent.

During the wars with France, from 1797, when the Bank Restriction Act was passed, to 1819, great fluctuation took place in the market value of gold, and nearly all gold coin was banished from the Country; the silver coin was also much depreciated in value, either through wear or unfair means, so that it would be useless to attempt any comparison during that period; but since the return of money payments the prices both of gold and silver have been nearly stationary, as appears from the following Table, which shows the market price of both metals, and the quantity and amount of each coined at the Royal Mint for each year, from 1820 to 1831 inclusive.

Manufac-
tures.
Process of
coining.

(873.) *Process of coining.*—The Art of Coining is of great antiquity, as is evident from the many ancient coins still preserved in our museums, but it was performed only by hand, with a hammer, and was a slow and imperfect process, proofs of which are frequently exhibited by the impressions on the reverse sides not being opposite to each other. The hand hammer, however, was the only method known till the time of Henry II. of France, in whose reign the coining-mill was first invented by Antonine Brucher, a French engraver, the first money struck by a mill or press bearing the date 1553. Like most other important inventions, however, many objections were made to it, particularly to the expense with which it was attended, and it was accordingly, after having been in use for about thirty-two years, laid aside by Henry III., in 1585, and was not again revived in that Country till the year 1645, by Louis XIV. The press was, in the interval, introduced into England by Elizabeth, in 1562, but, as in France, it was afterwards laid aside, and the process by hammer again had recourse to. In the year 1662 the mill was again put in force, and no other means have been since employed, although the machinery itself has undergone great changes, and has received various improvements.

Puncheon,
die, and
matrix.

The Ancients employed a sunken die, but different from the present, insomuch as the sunken part was made by the cutter or engraver; whereas the modern practice is to employ a puncheon, which is of highly-tempered steel, and on this the impression intended to be made on the coin is cut in relievo. It is then stamped on another piece, called the matrix, which is also of steel, four or five inches long, square at the bottom, and round at the top. The moulding of the border is afterwards added on the matrix with small sharp steel puncheons. When thus completed it forms the die. This saves much labour in repeatedly engraving, for it frequently happens, with striking the first coin, the die breaks, and, but for this provision, a new engraving would be required; moreover, as it would be almost impossible to engrave several dies all exactly alike, but one die could be employed at a time without introducing great variety, and thus facilitating the object of the false coiner. It is not certain when this improvement was first introduced, although it is certainly an important one in the Art of Coining.

Milling the
edges.

Another improvement in the coiner's Art, of somewhat modern date, is that of milling or ornamenting the edges, which was intended as a protection against what was called clipping and filing the King's coin—a fraudulent process, by which the weight and value of the several pieces have been much reduced; other means, however, have been contrived for effecting this object, as appears by the report of Mr. Hatchett, given in a preceding part of this article. It must, however, have contributed in part towards the prevention, and it adds greatly to the beauty and perfection of the coin as a work of Art. Its first introduction at the English Mint appears to have been about the year 1650, by Simon, an ingenious English engraver, who first exhibited it in the crown and half-crown pieces of that period, but it had been practised before. The first piece yet known as an instance of it is a silver coin of Charles IX. of France, dated 1573; and the first medal is one of silver, of George Frederic, Marquis of Brandenburg, dated 1589. Briot, a French artist, gave the first specimen of it upon his Scottish coronation medal in 1633; and Simon, as we have just mentioned, introduced it into the larger coins at the

VOL. VIII.

period above stated. The means which he employed are not known; but in 1685 a very ingenious machine was invented for the purpose by M. Castaing; it was first introduced into the Mint in France, and afterwards into the English, and most of the other Mints of Europe. There is, perhaps, no one of the mechanical Arts which have undergone greater changes and improvements than that of coining; and, in order that the reader may the better comprehend and appreciate these changes, we shall give a description of the methods practised in the British Mint in the Tower, from its first establishment to the year 1811, when a new building was erected on Tower Hill, and an entire new process introduced.

Mechanical
Processes.

(874.) The first step, after properly assaying the metals, was that of melting and mixing them in a furnace; they were then cast into bars of proper length, and it appears that the casting was made in sand, as in other founderies; the bars were afterwards reduced by rolls as nearly as possible to their proper thickness, the gold bars having been heated again before they underwent the last process, but the silver plates and copper bars were passed through the rolls without heating.

Former
method of
coining by
hand-
presses.

The plates, whether gold, silver, or copper, being thus reduced as nearly as possible to the proper thickness, were cut into round pieces, or blanks, by a machine called a fly-press, as described under the article Button-making, the process being in fact exactly similar; but in coining, as greater accuracy is requisite in the result, so greater perfection is also necessary in the machinery. A few blanks were first cut, and examined as to weight, and, if they were generally too heavy, the bars were returned to the rolls, and these adjusted so as still further to reduce the thickness, and consequently the weight, of the blank; and if they were too light the bar was re-melted.

The proper thickness having been thus obtained, the process of cutting the blanks proceeded, and they were successively transferred to the proper officers to be adjusted, and brought, by filing the edges, to the weight of the standard whereby they were to be regulated. The remainder of the plate between the holes left by the blank was remelted again, under the denomination of *sizel*. The pieces were adjusted by a very fine balance; and those which proved too light were separated from the general mass, as were also any which were found too heavy, the former to be re-melted, and the latter to be adjusted to the proper weight. The extreme accuracy, however, of the present machinery in the Royal Mint has greatly reduced all this preliminary labour, although with the utmost attainable exactitude it is impossible to have the rollers so exact that there may not be a trifling difference in the thickness of the bar, and a difference of weight in the blanks, to dispense entirely with this examination in operating on the precious metals. The blanks, having been adjusted, were carried to the blanching house, where the gold blanks were brought to their proper colour, and the silver ones whitened, which operation was performed by heating them in a furnace, and, when cooled, boiling them successively in two copper vessels, with water, common salt, and tartar, and after that scouring them, and lastly washing them in cold water, drying them over a wood fire, in a copper sieve, in which they were put when taken out of the boiler.

The next operation was the milling on the edges; this, till lately, was performed by a machine, which, by the constitution of the Mint, was not shown to visitors,

4 K

Manufac-
tures.

although there is no doubt it was the same as that used in foreign Mints, where no secret is made of the process. It consisted of two plates of steel in the form of rulers, on which the edging is engraved, half on one side and half on the other. One of these plates is immovable, being strongly bound with screws to a copper plate, on a board or table; the other is movable, and slides on the copper plate by means of a handle, and a wheel or pinion of iron, the teeth of which engage in other teeth on the surface of the sliding plate. The planchet or blank, being placed horizontally between these two plates, is carried along by the action of the movable one; so that by the time it has made half a turn it is marked all round. This process is greatly improved in modern coining.

Stamping.

The next operation was that of stamping; this was effected by a machine consisting of a beam, screw, arbor, &c., contained within the body of it, except the first, which is a long iron bar, with a heavy ball of metal at each end, and rings, to which were fastened cords, to give it motion; in fact a fly-press in principle, but heavier, and differing somewhat in form from that described under (Art. 863.) The bar here was placed over the body of the machine; in the middle of the beam was fastened a screw, which, by turning the beam, served to press the arbor under it; to the lower end of the arbor, placed perpendicularly, was fastened the die or matrix of the reverse or arm side, in a kind of box or case, in which it was retained by screws, and under this was the box containing the die of the image side, firmly fixed to the lower part of the machine. When the blank was to be stamped it was laid by hand upon the lower die; two men then, pulling the rope attached to the fly-beam or lever of the press, forced down the upper die with great violence, and consequently the blank placed between them received at once, as at present, an impression on both sides, which completed the operation. Such is a general view of the former process of coining as it was carried on for many years, viz., from about 1662 to 1811, in the Tower of London; but in the latter years, as already stated, a new, elegant, and appropriate building having been erected on Tower Hill, and new machinery for the purpose placed therein by Messrs. Boulton and Watt, a new and improved process has been adopted from that time; although such has been the progress of mechanical invention since that period that several of these machines have been greatly improved by English engineers in the construction of some foreign Mints, the most recent of which is described in a subsequent page.

Origin of
the modern
machinery.

(875.) The origin of the new machinery dates a few years prior to the commencement of the present century, when Messrs. Boulton and Watt began to apply the power of the steam-engine at their manufactory at Soho to the operation of coining, and afterwards coined a large quantity of twopenny and penny pieces of copper, and halfpence and farthings, for Government, many of which are still in circulation. They also, a few years afterwards, recoined a considerable number of Spanish dollars for the Bank of England without first obliterating the former impression by rolling, or otherwise than by the restamping. They likewise constructed a complete coining apparatus for the Danish Government, and subsequently another for that of Russia.

This extraordinary effort of a private manufactory, and the circumstance of the new machinery being adopted by foreign nations, while our own Mint continued to proceed upon the old and imperfect method, was strongly

noticed by the late Lord Liverpool in a published letter to his Majesty George III., where his Lordship observes, "But the new machinery now employed in the manufactory of every sort of metal, in which the mechanics of this Country far surpass those of any other, has not in general been admitted into your Majesty's Mint. It is an acknowledged principle that machines that act with a given force can work with more truth and accuracy than the arm of man, the force of which necessarily varies occasionally, from several causes. Another practice has been invented, that of striking coins in a steel collar, so as to make them perfectly round, and all precisely of the same diameter, an improvement which certainly contributes to the beauty of the coin; new modes of putting what is called the graining on the edges of the coins have also been invented, which, at the same time that they protect the coins from being filed equally with the present mode, do not occasion those rough edges, which expose them to wear by abrasion or friction. For these, and many other valuable improvements, the public are indebted to the ingenuity of Mr. Boulton, of Soho, near Birmingham. It is singular that, though the manufactures of England have greatly profited by these inventions, the officers of your Majesty's Mint have never, or not sufficiently, availed themselves of them; the Mints in foreign Countries are in search of them, and their Governments, in more than one instance, have employed Mr. Boulton in erecting Mints on his new principle; and Parliament has authorized the same."—Earl of Liverpool, *Treatise on the Coins of the Realm*.

It was, probably, in consequence of these remarks, and the attention thus drawn to the subject, that orders were given for the new building and the new machinery; but, as above observed, such has been since the progress of mechanics in this Country, that even this new machinery, so justly admired when first constructed, is now itself comparatively old and imperfect with respect to other Mints since constructed for different foreign Powers by English engineers, of which latter Mr. Hague, of Cable-street, Ratcliffe, has made several, viz., for Holland, Prussia, Brazil, &c. We have been obligingly furnished by that gentleman with the description and drawings of a Mint he is at this time engaged in constructing, to be erected at Rio Janeiro, which is perhaps one of the most perfect pieces of machinery of the kind at present known. We propose, however, before entering upon a description of it, to present the reader with an account of the Royal Mint, with a survey of which we have been favoured.

(876.) *Description of the Royal Mint.*—The first business attended to in this Establishment is the assaying of the bullion, as it is received from the Bank of England, which takes place in the Essay Office of the Master of the Mint: it is here received into what is called the strong hold, and there kept till its fineness is ascertained, in order that its true value may be computed. This being determined, the parties concerned are requested to attend the office of receipt and delivery, to witness its weight, and to be informed of its fineness, and consequently of its value; a Mint bill is then made out, and given to the owner, by which he knows the exact value of his deposit.

The next step is the delivery of the bullion to the melting-house, which is furnished with all the requisite furnaces and apparatus, adapted not only to the melting of the gold and silver, but also with cranes for lifting it out of the furnace, mould, patterns, &c. But there is

Mechanical
Processes

Description
of the Royal
Mint.

Manufactures. nothing very particular in this part requiring minute description. It will be sufficient to observe that the furnaces in which the metal is melted are eight in number, and are arranged on opposite sides of the melting-house, in two rows of four each, a swinging crane being placed in the centre between four, which, by turning on its centre, comes over the centre of any one of the furnaces, and lifts a pot of melted metal, weighing about 400 pounds, from any one of the four, and by which it is conducted to the pouring machine.

This last named is an iron frame, in which is an iron hoop, turning on an axis on each side; into this hoop the melting-pot is received, and, by means of a screw, the hoop is made to embrace the pot tightly at the top, under its upper flanch; from the hoop descends a bar of iron; and to these again is connected, on the other side, an arch, on which teeth are cut; and in these a pinion plays, by means of which, and proper wheel-work, the pot may be inclined at any angle, and the metal thereby poured out in iron moulds, mounted in a frame, on wheels, by which they are successively advanced to receive the metal as the others are filled. The ingot moulds are of cast iron, each in two halves, having flat surfaces, to form the faces of the ingot; and rising edges, to form the sides, and another to form the bottom; whereby any number of them being placed contiguous, and confined together with screws in the frame, the same number, or rather the same number minus one, of moulds are formed; these all rest on the bottom of the carriage above described, to preserve them of the same height, but which may be adjusted at pleasure, to suit moulds of different sizes. The ingots, being thus formed, are transferred to the rolling-mill. The metal is melted in pots of cast iron. Commonly the silver is run into plates ten inches long, seven inches wide, and about half or five-eighths of an inch thick. The gold plates are ten inches long, four inches broad, and three-eighths thick. While the metal is pouring into the mould there are three portions taken from the top, the middle, and the bottom, and carried to the King's Essay Office, to be examined by the officer, to ascertain that the proper standard value is preserved.

Before quitting this part of the establishment we may observe that formerly, if not at present, in the process of melting there would necessarily be some waste; every thing, therefore, that can possibly contain any portion of the precious metals, such as the sweeping of the smelting-house, &c., is collected and carried to another apartment, in which are erected two grinding and two triturating mills, where the sweep is worked up, and the fine metals in part recovered, in the manner practised by refiners and goldsmiths.

The sweep thus brought together is ground into a powder, and passed through a fine sieve, by which the larger grains of metal are obtained. The sweep is then put, in small portions, into a wooden bowl, having two iron handles, by which it is carefully washed: the lighter particles, being absorbed by water, are collected in a large tub; the heavy, or metallic ones, are found deposited at the bottom of the bowl. By these means the most considerable of the particles of gold or silver are obtained. The powdered sweepings, however, which have been collected after the washing process, still contain portions of metal; to obtain these the sweep, in certain portions, is put into a mill, containing, generally, about one hundred weight of mercury, the remainder of the mill being filled with water; this is commonly called

the triturating mill; and each charge is agitated about four hours with an iron instrument, having four arms placed horizontally, in the shape of a cross, and fixed to the centre of the mill; and, for the better agitation of the sweep of the mercury, the motion of this mill can be reversed at pleasure.

The next process is the rolling; and the ingots, formed as above, are therefore transferred to the rolling-room, which is furnished with four pair of rolls, driven by a steam-engine of thirty-horse power. One pair of these rolls is shown in fig. 10, plate lvii. The two shafts are situated parallel to each other, and receive their motion from the engine. It is an excellent construction, executed by the late John Rennie, Esq.; but, except in the extreme accuracy and perfection of the workmanship, there is no difference between this and another rolling-mill; they therefore require no particular description.

Opposite to each pair of rollers is a furnace, into which the silver ingots are introduced, and heated to redness before being submitted to the rolls; they are then taken from the furnace, one at a time, and the rollers being adjusted to a proper distance, they are applied, with the longest side of the ingot to the rollers; this is caught again on the other side, in a pair of tongs, by another workman, passed over the top to the first, who again passes it to the other, and so on, the rollers being adjusted as the thickness is reduced, till, at length, what was at the beginning the length of the plate becomes its breadth, the rollers only stretching the metal in the direction of their motion; the plate, therefore, which was at first ten inches by seven, comes out about twenty-eight inches by ten, and consequently proportionally reduced in thickness. These first rollers, which work the metal hot, and serve to consolidate it, are called thereby breaking-down rollers. The plates, whilst still warm, are rubbed over with a weak solution of acid, to remove the colour produced by the heat; they are then cut up into narrow slips, according to the nature of the coin contemplated, by means of a pair of circular shears.

These are represented in fig. 11, plate lvii. The Circular machine is worked by a cog wheel at the extremity of the main shaft of the rolling-mill. It consists of a framing of iron A A, supporting two shafts B B, which are parallel to each other, and move together by means of two cog wheels C C. At the extremity of these two shafts are fixed circular cutters D E, overlapping each other a small quantity, as shown in fig. 12, where it is seen that each cutter has a rim of smaller diameter than the outside; this small rim of the upper cutter is behind it, at *e*, but is in front of the lower one, at *g*, so that the adjacent edges of the large rims, *f* and *k*, come in contact, and overlap each other a very little; by this means they act as a pair of shears, to cut any thing placed between them. The metal plate being therefore laid down against the straight edge or guide plate F, which is adjustable according to the required breadth, and the plate being once applied to the revolving cutters, they draw it forwards, dividing it into two strips, *c d*. Fig. 12 shows a section of the plate. The part *c* is conveyed from the top of the rim *k* of the lower cutter, and kept from rising by the small diameter *e* of the upper cutter; at the same time the upper part of the plate is depressed by the rim *f* of the upper cutter, and supported by the small rim *g* of the lower one. By this means the divided parts are prevented from coiling up into scrolls, as they would do without these precautions. The frame *l*, and screw *m*,

Mechanical Processes.

Rollers. Pl. lvii. Fig. 10.

shears. Fig. 11, 12.

Manufac-
tures.

serve for keeping the edges of the cutters in proper contact. The strips of metal being thus formed are taken to the other rollers, called burnishing rollers, where they are further reduced cold, and brought as nearly as possible to the proper thickness, being constantly applied to gauges to ascertain the progress of the reduction, the rollers being successively adjusted as the work proceeds.

Drawing
machine.

(877.) *Drawing machine.*—Notwithstanding all the care that can be bestowed at the rolling, some inaccuracy will be found in the thickness of different parts of the same metal plate, and, therefore, as a last process, each is now passed through a drawing machine, which was not a part of the original construction, but was afterwards added on the suggestion of Mr. Hague; it was, however, executed by Mr. Maudslay. It is a heavy cast-iron frame, standing three feet above the floor, and about twenty feet in length, with a well-planed upper surface, on which a carriage runs with great accuracy, the latter being furnished with jaws resembling those of a vice, which are made by means of screws to take a firm hold of the bar, which is reduced a little in thickness at the end, to pass it through the two fixed plates, through which it is to be drawn. These plates are fixed in a frame securely attached to the end of the long drawing frame above referred to, the plates themselves being adjustable by screws to the utmost degree of accuracy.

The carriage, furnished with two pair of wheels or rollers, moves on the two plane faces of the long frame, and in the opening between these is a long endless chain, which passes over rollers at each end of the frame: the chain passes above nearly on a level with the upper face of the machine, and returns below under the floor. The chain is double, each link resembling a clock chain, and the two are united by strong iron bars, at about a foot distance, their length being of course equal to the distance of the two chains, viz., about six inches. The steam-engine being put in motion gives rotation to the rollers, and these to the chain, which is not, however, in connection with the carriage till that connection is established by an apparatus attached to the latter, which turns on a joint on the carriage, and which is so balanced that, when free, the heavier part falls on the carriage itself. Suppose now a rod or plate of metal to have been passed through the plates and secured in the jaws of the drawing carriage, the apparatus above referred to is tilted down, and being furnished with a proper hook at the depressed end, this catches hold of one of the cross bars of the chain, and thus connects the latter with the carriage, and by the motion of the former the rod is drawn through the plates, and reduced to a uniform thickness, which could never be attained with revolving rollers. It should be observed that, the rod having passed through, the carriage has a tendency to start forward, and the apparatus we have mentioned, which is attached to the carriage, is relieved from its hold on the chain, and, being heaviest at the other end, it tilts up and is perfectly free, the two being thus disunited till another rod or plate is introduced, and the hook end again depressed by hand.

The plate being drawn through, there are in the same room several little hand-presses for cutting out a few trial blanks, which are taken to the Essay Office, and, if found too heavy, the plates are readjusted, and the rod drawn again till the proper thickness is obtained, and this, being determined in one case, is sure to be found so throughout, so that the tiresome and unscientific process

of adjusting the weight by the file is wholly, we believe, Mechanical dispensed with. It will, of course, be understood that Processes. this accuracy is not necessary in the copper coinage.

The thickness of the rods being thus adjusted, they are taken to the cutting-out house, in which are situated twelve cutting-out presses. They are arranged in a circle, with a strong iron vertical axle or shaft in the centre, carrying a heavy fly-wheel at its upper end; this is put in rotation by the steam-engine, and, being furnished with a coin, strikes the levers of the several presses in succession, and thereby cuts out the blanks, which fall into boxes beneath. The other end of the press lever is connected with a strong spring, which is charged or stretched by the same motion which depresses the cutter, and immediately the coin passes, this spring again raises the cutter, to be again in like manner depressed by the following coin, and so on, a boy gradually urging the plate forwards as the blanks are cut out. We shall not enter more particularly into a description of this machine, as we intend to describe a more recent one just completed for the mint of Rio Janeiro. The blanks in this state are taken to the annealing furnace, having been rendered too hard by the previous operations of rolling, drawing, &c., to receive the impression at the stamping-mill without this process.

The blanks being thus prepared are put into a sizing or milling machine, but this, like the old milling engine, is, by the constitution of the Mint, not shown to visitors, but we shall, in our subsequent description, explain that used at the mints constructed by Mr. Hague. It may be observed, however, that the sizing is only done to thicken, or what is called to upset the edge, in order to give a bold projecting edge to the coin, to protect the raised part of the impression. The milling on its edge being effected now at the same time the impression is raised by the coin being struck in a collar already milled.

It only now remains to describe the last process of stamping, the machinery for effecting which is by far the most elegant in the establishment. In this room four presses are ranged in a line along its centre, all resting on one solid stone basement. The nature of the press in its general operation differs in no other way from the common fly-press than in its motion from steam power, instead of by hand, as described in the old method, but there are several appendages to it which are very interesting. On the old principle the blanks were laid by hand, one by one, on the lower die, which necessarily rendered the operation slow, as great accuracy was required in placing them, and great danger to be apprehended if the press descended before the hand was removed. This evil is now very completely removed by what is termed a feeding apparatus, worked by the machine itself. A tube is placed in front of the machine, of exactly the diameter of the blanks to be coined, and into which two or three dozen blanks may be put, and others supplied occasionally by a boy, a few at a time, as the work proceeds—an operation entirely free from any danger; under the tube passes a slider, which is thrown backward and forward by an excentric on the shaft at every blow of the press: in the slide is a hole the exact size of the coin, and when, by the sliding motion, this comes under the tube, the lower blank in the same drops in, which is then urged forward by the slider on a base level with the top of the die till it is exactly over it, all which distances are accurately adjustable by proper screws, &c.: having placed it there, the slide is with-

Manufac-
tures.

drawn, but it is so contrived that the first effort to withdraw it opens the two parts which shut to form the circular hole, whereby the blank is left behind, and, as the slide returns, the parts which were opened again close and receive the next blank, which, as it advances, pushes away the last, which has now received its impression, and deposits another blank in its place.

We have said that every blank is struck in a collar; to effect this another appendage is requisite; but, as we shall explain this particularly in our description of the Rio Janeiro Mint, it will be sufficient to observe here, that, while the press is descending to make the impression, the collar rises from below to embrace the blank placed thereon, and after the impression is given, and during the ascending motion of the press, the collar is forced down again, leaving the stamped coin lying on the top of the die till pushed off by the feeding slider above described. By this means the milling on the edge is rendered very perfect, the rim of the coin is bold and projecting, and the utmost accuracy is attained in the size of the pieces. This completes the process, and we shall now proceed to describe rather more minutely than we have hitherto done the particular means employed to produce these effects according to the most recent and most perfect means.

Hague's
coining
apparatus.

(878.) *Coining apparatus by Mr. Hague.*—The complete apparatus, as supplied by the above ingenious mechanist, includes rolling-mills, drawing frame, cutting-out machine, milling machine, and stamping presses, but the two former differ so little from those which have been already mentioned that we shall confine our description altogether to those machines which are peculiar to coining, namely, the cutting-out machine, the milling or sizing machine, and the stamping presses.

Sizing
machine.
Pl. lvii.
Fig. 13, 14.

Sizing machine.—This is an extremely simple apparatus, exhibited in plan and section in fig. 13 and 14. A B is a substantial cast-iron frame, within which a wheel W revolves, leaving a certain and determinate distance between its circumference and a recess in the metal, the distance being of course alterable to the size of any proposed coin. The blanks are dropped in at the top, the wheel W being in motion, and are carried along with it in its motion, and reduced in their progress to the exact breadth intended, by which means their edges are thickened, and the bold and protecting rim of modern coins produced. At the bottom of the groove is a hole h, through which the blank passes to a drawer beneath.

Cutting-out
machine.
Pl. lviii.

Fig. 1 and 2, plate lviii. are the elevation and ground plan of one of the cutting-out machines, which are situated in a line parallel to each other, and are raised above the ground a sufficient height to permit the attendant to work in a convenient position. A A is a massive frame of cast iron, which is very firmly bedded upon masonry B B, and contains an interior screw, into which is accurately fitted a screw situated on the axle C C; but, in order to insure the perfectly vertical motion of the shaft, the part on which the screw is formed only extends for a short part on the middle of the shaft, and the upper and lower end are cylindrical, and turned perfectly true in a lathe; the opening for the shaft in the cast-iron framing is made considerably larger than the shaft, to leave room for its adjustment, which is effected by the screws a a a, situated at the upper and lower end, and thus any inaccuracies from wear, or any other cause, may be rectified, and a perfectly vertical motion of the shaft secured. The stamper and die do not differ from those commonly employed, except that the latter is si-

tuated within a cast-iron circular frame D D, furnished with screws for the purpose of adjustment.

Mechanical
Processes.

We have now to describe the manner of giving motion to the vertical shaft C C, which is the part where this machine differs most essentially from the common construction. E E is a hollow cast-iron pillar, firmly secured to the masonry by bolts d d, &c., in which a vacuum is continually kept by means of a pipe F, which communicates with an air-pump of the steam engine; G G is a cylinder having hollow axles, which vibrate in bearings in the hollow cast-iron frame H H, connected with the pillar E E, and thus, through the intervention of a pipe K, the air is exhausted in the cylinder when required, and a reciprocating motion given to the piston. The motion thus given to the piston is converted into a rotary motion by means of a crank attached to the vertical shaft L L, and this again, by means of a rod M M, communicates an alternating motion to the crank N in the arch of a circle, and consequently a vertical reciprocating motion to the shaft C C, the extent of which is varied according to the part of the crank to which the rod M M is attached. The cylinder G G is provided with flat pipes b b, which extend from each end to the hollow axle, and the axle is provided with apertures, so arranged with respect to that of the pipe K, that the cylinder is in connection with the vacuum during the descent of the piston, but, on its return, communicates with the atmosphere, so that the piston is free to return by the momentum of the fly-wheel P P. At the time it arrives at the top of the stroke the aperture of the hollow axle is again opposite the pipe K, so that the cylinder is in connection with the vacuum, and the piston again descends with the whole pressure of the atmosphere, and thus a rapid succession of blows is given by the stamper as the workman exposes a new part of the plate to its action.

In plate lix. fig. 1, is given an elevation of the coining machines, of which there are eight, situated at equal distances round a circular cast-iron vacuum chamber A A A. The framework of the machines B B, B B, &c., is of cast iron, and of the figure shown in the drawing, and each machine is secured to a solid mass of masonry which surrounds the vacuum chamber. The vertical shafts C C work in interior screws in the upper part of the framework, and are guided in their vertical motion by adjusting screws at the upper and lower extremity in the same manner as in the cutting-out machine. E E, &c., are drums situated on the vertical shafts, from which chains extend to the piston of the cylinders D D, &c., attached to the vacuum chamber, and serve, by the aid of the vacuum, to give motion to the stampers. To each vertical shaft is attached a fly-wheel F, which serves, by its momentum, to increase the blow given by the stamper, and at the same time too, by means of pins projecting from it, which strike levers connected with the valves G, effects a communication at the proper part of the stroke with the cylinders and the vacuum chamber; that is to say, during the descent of the piston the cylinder and chamber are connected with each other, but when it has arrived at the bottom of the stroke, the pin on the fly-wheel strikes the levers and changes the position of the valves, so that both top and bottom of the piston are in communication with the atmosphere, and the screw and stamper are free to return. When the piston arrives at the top of the stroke, another pin on the fly-wheel comes in contact with the levers, and throws them back into their original position, by which the cylinder is again put in communication with the chamber, and the

Coining
machine.
Pl. lix.
Fig. 1.

Manu-
factures.

piston again returns with the full force of the atmosphere, and thus a constant succession of blows is kept upon each coin as it is introduced into the die.

There now remains to describe the manner in which the coin is introduced into the die before each blow is struck, and afterwards removed in order to give place to its neighbour:—*a* is a cast-iron box, situated on a level with the surface of the lower die, and *b* is a vertical lever which turns upon a bearing *c* attached to the frame, and receives a vibrating motion by means of an excentric *d* on the vertical axle *C*. To the bottom of this lever a flat horizontal arm extends into the box *a*, which contains an opening a little larger than the coin, and is of such a length that, when the lower end of the lever is in the position nearest the vertical shaft, the opening in the arm exactly coincides with the die; and when in the reverse position, *viz.*, when furthest from the centre of the machine, the opening corresponds with that of a tube *e*, in which the pieces of metal intended to be coined are situated. The bottom of the box is made inclined during a portion of the length, but is horizontal in the part situated nearest the die, which causes the horizontal lever, when it commences its return, to tilt up, and leave the coin which it has received in opening from the tube *e* in its proper situation in the lower die to receive the impression of the stamper. On its return it receives another piece of metal from the tube, which it conveys to the die, and pushes away the former piece of metal, which has been freed from the die by the following contrivance:—The lower die, which is formed on a cylinder the exact size of the coin, is surrounded by a collar which contains the impression to form the rim. This collar is attached by two levers, *ff*, to vertical rods *gg*, which are connected with a powerful spiral spring situated in the masonry below the machine, and to a cylinder *hh*, which forms a continuation of the vertical axle *C*, and has attached to it at the lower end the upper die or stamper. This cylinder works in a frame *kk*, which can be adjusted by screws, so that the upper and lower die exactly correspond with each other. When the shaft *C* descends by the force of the air cylinder it compresses the spiral spring, and at the same time raises the collar above the die a sufficient height to form a reception for the coin which has the instant before been left in its position by the lever above described; but the moment the blow is struck the vertical shaft is returned by its own reaction, assisted by the spring, which, in relapsing, forces the collar down, and leaves the coin free to be pushed off by the lever as it advances with a fresh piece of metal to be coined.

Clock and Watch-making.

Clock and
watch-
making.

(879.) Some means of measuring and subdividing time may be considered amongst the wants of civilized society, and it is accordingly found that methods and machines intended to accomplish this object are of very early origin. Of these instances are recorded in the Bible, such, for example, as sun-dials. We have, then, the clepsydra of the Egyptians and Greeks, the hour-glass, and other like approximative means. It was no doubt many years afterwards before the thought occurred of employing the natural force of gravity on a descending weight to effect the same object, and still later the introduction of the spring. The number of years which have passed even since the latter discovery have led to great perfection, and the extreme

accuracy which is now attained in the modern clock, which works on, day after day, for several days, and even weeks, without an error amounting to the fraction of a second per day, justly claims for this machine a very high rank as a work of Art; in fact it must be considered one of the most accurate and most perfect instruments due to human skill and ingenuity.

The term clock is generally applied to those time-pieces in which the motive power is a descending weight, and the regulating power a pendulum; and under this denomination we shall confine our description to such machines only; but, subsequently the watch, and other horological machines, will be illustrated and described.

The honour of the invention of the clock constructed according to the above definition, *viz.*, whose motive power was a weight, and regulated by some description of governor, is ascribed to different persons. According to some writers we are said to owe the discovery to Archimedes and Posidonius, while others ascribe the invention to Boethius, in the Vth Century; but this, from some remarks of the author, Hamberger supposes to have been a clepsydra, or water-clock, and not a clock moved by wheels and weights.

Invention
ascribed to
Boethius.

The machine sent as a present to Charlemagne by the King of Persia, in the year 807, is supposed by some to have been a clock like those used at present. This, however, like the former, Hamberger considers to have been nothing more than a water-clock, furnished with some ingenious mechanism, but having nothing in common with our clocks.

About the same period lived Pacificus, Archdeacon of Verona, who is celebrated for having invented a clock. His epitaph, besides relating other services which he performed, says,

Clock in-
vented by
Pacificus

*Horologium nocturnum nullus ante viderat,
Et invenit argumentum et primus fundaverat;
Horologioque carmen spheræ cæli optimum
Plura alia graviaque prudens invenit.*

Scipio Maffei considers that a clock moved by wheels and weights is here referred to. "This horologium," he remarks, "the like of which had been never seen, and which was different from a sun-dial because it showed the hours in the night-time, could not be a clepsydra or water-clock, for these were not only known to the Ancients, but even to the inhabitants of Italy, in earlier times; so that it could have been nothing but a clock like ours." It is argued, in reply to this, that, although water-clocks were known in Italy at that period, it is evident they were employed only by very few people, as stated in the writing of Cassiodorus on this subject. Moreover, that too much importance is attached to the words of the epitaph, *nullus ante viderat*, and that they might indicate but a slight difference in the construction.

Some ascribe the invention of our modern clocks to Gerbert, who in the Xth Century was raised to the Pontifical Chair at Rome, under the name of Silvester II., and who was reckoned to be the first mathematician and astronomer of his time. This, however, is only mere conjecture.

Invention
ascribed to
Gerbert in
the Xth
Century.

Among so great a variety of opinions and contradictions it is impossible to learn to whom we are indebted for the first idea of the modern system of clock-making. Hamberger states that there is no doubt clocks were in use in the Monasteries in Europe about the XIth Century; and that it is probable Europe is not entitled to the

Manufactures.

Clock by Wallingfort.

Clock by Henry de Wyck.

Description of De Wyck's clock. Pl. lx. Fig. 1, 2.

honour of the invention; but that it is rather to be ascribed to the Saracens, to whom we are indebted for many of the Mathematical Sciences.

The most ancient clock with wheels and balances mentioned in history, and of which the existence is positively known, was constructed in England by Richard Wallingfort, Abbot of Saint Alban, who lived in 1326.

Charles V., surnamed the Wise, King of France, caused, in the year 1370, a large clock to be placed in the tower of his palace by Henry de Wyck, whom he invited from Germany, because there was then at Paris no artist of that kind, and to whom he allowed a salary of six sols per day, with free lodging in the tower.

The precise construction of the clock of Wallingfort does not appear to have been handed down to us, but the description of the one last mentioned, by Henry de Wyck, is given at considerable length by Berthould, which, as forming not only a very interesting historical fact, but being serviceable in giving the reader an idea of clocks constructed on the modern principle, we translate from the author's own words.

(880.) In fig. 1 and 2 of plate lx. are given a front and side elevation of this machine. A is a weight suspended by a cord which is folded round a metallic barrel B, the axle of which has bearings in holes in the plates C C, D D. These plates were in the first clocks made of iron, and attached by being bent above and below at right angles, and which thus formed the frame.

The action of the weight A has a natural tendency to turn the cylinder B, and if it was not retained its descent would be by an accelerated motion; but this cylinder carries a catch wheel F, seen in fig. 1, the teeth of which engage the click c attached to the wheel C by a screw. The click is furnished with a spring, which, by exerting a pressure on the click, causes it always to engage the teeth of the wheel. This mechanism is for the purpose of winding up the clock. The action of the weight is in this way transmitted to the toothed wheel G, and from thence by a pinion e to a toothed wheel on the axle ff; this wheel again transmits the motion by a lantern pinion g to the wheel II, fixed on its arbor, which is called the crown or escapement wheel. This last wheel, by giving the pallets or short levers ik a motion alternately in opposite directions, produces a vibratory motion to the vertical arbor k, and, as the regulator or balance was fixed in this arbor, it was thus made to vibrate backwards and forwards at every push of the crown wheel upon the pallets. The pallets are placed upon the vertical arbor at an angle of about 90°, so that, when one of the teeth has passed the pallet, the other pallet presents itself to a tooth diametrically opposite, to be acted upon in its turn. This action of the crown wheel upon the pallets, which escaped the teeth alternately, was termed the escapement, or, by abbreviation, scapement of the clock; it is by means of it that the large weight is prevented from falling with rapidity to the ground by giving it a check, at every impulse of the wheel of escapement, on one or other of the two pallets; and the interval between two successive impulses being regulated by the time of a vibration of the balance, which could be adjusted by weights mm, fig. 2, placed at different distances on the arms L L of the balance, in notches made for the purpose, if the vibrations were too quick the momentum of the balance was increased by removing the suspended weights further from the centre of motion, and *vice versa*. As the balance was necessarily heavy to regulate a large maintaining power, the best

means of avoiding the friction became a consideration: Mechanical Processes. it was effected by suspending it by a cord, so that only part of its weight was borne by the lower pivot.

The clock was so contrived that the wheel G G made one revolution in an hour: the pivot b of this wheel extended outside of the plate, and had attached to it a pinion d, which engaged the wheel N N, and caused it to make one revolution in twelve hours; the axle of this wheel carried the index or hand O, which marked the hours on the dial.

The wheels and pinions have thus two offices to perform: the one to transmit the maintaining power in order to continue the motion of the balance; and, secondly, to indicate them in a visible form by a hand. To comprehend the manner in which this latter object was accomplished let us suppose the balance to be caused to make one vibration in the space of a second by the adjustment of the movable weights mm. By giving thirty teeth to the crown wheel I I it will make one revolution, while the balance makes sixty vibrations; for, at each revolution of the wheel, the same tooth acts once on the pallet h, and once on i, which produces two vibrations for each tooth, and thus, the wheel having thirty teeth, it is caused to make twice thirty vibrations; it therefore makes one revolution in a minute of time, and is required to make sixty revolutions during one of the wheel G. If the wheel G carries sixty-four teeth, and the pinion e eight, this pinion will make eight revolutions while the wheel has made one; and the wheel H having sixty, and the pinion g eight, it will give seven and a half revolutions to this pinion, on the wheel H, carried by the pinion e, makes eight turns for one of the wheel G; the pinion g therefore makes sixty revolutions during one of the wheel G; and, as we have seen that the wheel I I, carried by the pinion g, makes one revolution in a minute, it is evident the wheel G makes one revolution in an hour. On the same principle the pinion carried by the axle of the wheel G ought to make twelve revolutions while the wheel N N makes one, or have one-twelfth part the number of teeth on the circumference. While thus the train of wheels is transmitting the power of the suspended weight forwards to the balance, it is also counting the number of vibrations to constitute an hour which it points out on the dial-plate by a hand, a representation of which is given in fig. 3. A B are the plates of iron which are bent over at right angles at the top and bottom to form a framework for the wheels and pinions. The motive weight is suspended by a cord which is wound round the barrel G, which, like that employed in the clock, carries a click attached to the wheel H for the purpose of winding up the weight, the handle being placed on the square end of the axle of the pinion which engages the wheel I.

The wheel H carries twelve pins, b c, &c., which serve to elevate the hammer which strikes the bell: they are neither of them represented in the drawing, but it is easy to conceive an axle put in the frame which carries an arm which engages the pivot on the wheel H, and another to which is attached the hammer, and which, by this means, may be made to strike the bell.

The toothed wheel H engages the lantern d, fixed on the axle of the second wheel K, which also engages in the pinion e, the prolonged axle of which carries the fan L, which, by the resistance it experiences in the air, regulates the motion of the wheels, and the interval between each blow of the hammer.

The means by which the hammer is made to strike

Description of the striking part of De Wyck's clock. Fig. 3.

Manufac-
tures.

the correct number of blows in each hour were as follows:—The axle of the first wheel H was made to extend beyond the plate A, and carried a pinion of eight teeth, which engaged the wheel M, carrying seventy-eight teeth, so that this wheel made one revolution when the hammer had struck seventy-eight blows, or all the hours from one to twelve added together. On the axle of the wheel M was fixed another wheel, N, which had in the circumference twelve notches at unequal distances, varying in the proportion of the number of hours, 1, 2, 3, 4, &c. This last wheel regulated the number of blows which the hammer ought to strike at each hour. Over the circumference of the counting wheel N there was situated a detent *d*, having two claws, one of which reaches to the pins of the wheel N, and the other is situated within the frame directly over a single tooth *o*, on the axle of the fly L. Now, as the twelve-hour wheel revolves by the going part, one of its pins reaches the end of the long lever at every hour, depresses it, and at the same time raises the detent from the notch of the counting wheel, and also the short level V from its tooth *o*. The wheelwork, having nothing now to detain it, is immediately put in motion by the weight F, and continues to revolve until another notch of the count wheel arrives at the detent *a* which the detent falls into. The claw V again engages the tooth *o*, and the motion of the fly is stopped, and continues at rest until another hour elapses, when the detent is again raised from the twelve-hour wheel, and the striking machinery again put in motion, the same operation being repeated at every hour of the day, the number of blows of the hammer depending on the interval between the notches on the count wheel, which, as before stated, are arranged in the ratio of the number of hours, so that, the lever of the clock being so adjusted that twelve blows will be given while passing the largest interval, the number of blows struck at each succeeding hour will be correctly indicated.

This ingenious clock machinery, although, of course, much improved since this period, exhibits certainly a great effort of skill, considering the state of mechanics at the Age in which it was invented. About the year 1370 Strasburg had a clock, a description of which is given by Couland Dasypodius.

Clock at
Strasburg
in 1370.

Courtray
clock.

Courtray was about the same period also celebrated for its clock.

Clocks ap-
plied to as-
tronomical
purposes.

(881.) Public clocks were, soon after this period, erected in several of the principal cities of Europe, and in the year 1484 they had attained a sufficient degree of perfection to be useful for astronomical purposes, to which they were applied by Walther at Nuremburg.

Springs
used as a
motive
power.

About the commencement of the XVIth Century the spiral spring was first used as a prime mover, and the clocks were so much reduced in size as to become applicable to private houses; it is said that they were even made sufficiently small to be rendered portable, or, in fact, made in the shape of watches: it is not, however, probable that so great a change would be made at once, but that the reduction in size was gradually brought about, as the successive attempts were not found sensibly to affect the accuracy of the clock.

Fusee in-
vented.

(882.) When the spring was used as a first mover it was soon found that its power at the commencement of its action was much greater than towards the completion, and that an irregularity in the rate of the machine was in consequence produced. This naturally led to the invention of the fusee, which consists of a kind of cone upon which the chain from the spring is wound up, so that in

relapsing itself its force is exerted at a lever equal to the radius of the cone at the part at which the chain was situated. Thus, by reducing the diameter of the cone in an inverse ratio to the relaxing power of the spring, an equal degree of motive force was at all times exerted upon the machinery of the timekeeper.

Mechanical
Processes.

A clock upon this principle was some time ago in the possession of Mr. Pickett, of No. 50, Old Compton Street, which, from an inscription engraven in the Bohemian language, appears to have been made in the year 1525, by Jacob Leck, of Prague. It contained a spiral spring with a fusee of soft metal, and a screw at the end of the double levers of the balance for adjustment, instead of the movable weights we have described as being employed in De Wyck's clock. It had also some wheelwork to show the motions of the sun and moon in an engraven ecliptic, and also a contrivance to strike one at every hour. A catgut was originally the band of the fusee, and a modern metallic chain has been substituted, which has unfortunately destroyed nearly three out of the eight spiral threads at the smaller end; so that, instead of going forty-eight hours, (its former time,) the remaining five threads will only allow it to go thirty, which it now does, although irregularly, the vibrations being nearly one second each.

Beckmann, in his *History of Inventions*, mentions this clock as having been the property of Mr. Ferguson, at whose sale the present proprietor purchased it in the year 1777.

It appears probable that this construction of clock was not that first employed with the spiral spring, but that the unequal action of the latter was regulated by an additional spring, which, being disposed in a particular curve, opposed the principal spring when first wound up, and acted in the same direction with it as the intensity began to relax.

(883.) We have now to relate a most important event in the history of clock-making, viz., the discovery of the isochronal property of the pendulum by Galileo, which discovery may be fairly said to have laid the foundation of the modern system of clockwork, where, in availing ourselves of this property, a nearer approach to true time can be accomplished, even with rough work, than could be attained previously to this invention by the most accurate workmanship.

Isochronal
property of
the pendu-
lum dis-
covered by
Galileo.

The honour of the discovery of the properties of the pendulum is, without dispute, attributed to Galileo; but not so with its first application to clockwork, this being a subject of great contention; and it is to be regretted that, owing to the prejudiced opinions of most writers in favour of their own Countrymen, and the desire of attributing to them the honour of the discovery, the facts connected with it are so completely misrepresented that it is impossible to arrive at the truth with any degree of certainty.

Application
of the pen-
dulum to
clocks.

We are informed by Professor Venturi, *Essai sur les Ouvrages Physico-Mathématiques de Leonard de Vinci*, that Sanctorius applied a pendulum to clockwork some time before the year 1625. Vincentio Galileo, the son of the famous Galileo, is also said, *Exper. de l'Acad. del Cimento*, to have made a pendulum clock, suggested by his father's discovery, so early as the year 1649, at Venice; but Christian Huygens, the justly celebrated mathematician and philosopher of Zuylichem, contested the honour of the priority with him, which gave rise to the excellent Treatise on clockwork, *De Horologio Oscillatorio*, which laid the foundation of

First appli-
cation of
the pendu-
lum dis-
puted by
Galileo and
Huygens.

Manufac-
tures.

most of the subsequent improvements in horometrical machines, and in which it appears indubitably that he made, or directed the making, of a pendulum clock before the year 1658. From comparing what has been deduced by these two contending mathematicians, an impartial reader is led to conclude that Vincentio Galileo may have applied the pendulum in a rough, mechanical manner; but that Huygens's experiments were conducted more scientifically and perfectly; and probably without the knowledge of what his opponent had previously done: hence the honour of the invention has been generally attributed to Huygens.

He discovered that the isochronal property ascribed to the pendulum was only true in circular arcs of the same degree of vibration, and that a long arc required somewhat more time for a vibration than a short one, so that variations in the maintaining power produced variations in the time indicated, by altering the length of the arc of vibration of the pendulum. This inequality is so small as to be insensible in one vibration, and thus it was not detected by Galileo; but when the pendulum was employed to measure days, months, and years, the inequalities accumulated and seriously affected the accuracy of the clock. Huygens sought by the aid of Geometry the curve in which a body would descend in equal times in whatever part of the curve the oscillation commenced, and found it to be the cycloid, so that if the pendulum could be made to vibrate in the curve of a cycloid, the vibrations would be perfectly isochronal.

This discovery was very beautiful and important in a theoretical point of view, but its practical application, as a method to cause a pendulum to move in such a curve, was a matter of considerable difficulty. Huygens proposed the following ingenious method, which may be thus explained:—Suppose a thread is unwound by raising the extremity from a curve of any figure which it is caused to envelope, this extremity will describe another curve differing in properties from the first. Huygens found a curve was required from which, if a thread was unwound, the extremity would describe a cycloid. By this contrivance, which does high honour to the ingenuity as well as the science of Huygens, he caused the bob of the pendulum to vibrate in a true cycloid, but it has not been found of practical utility. Indeed, although the discovery of this law has been of infinite use in the Sciences of Astronomy and Geography, yet it has not in any degree been rendered practically useful in the construction of clocks until lately, by Mr. Frodsham, any further than that, by the knowledge of the irregularity of the vibrations in long and short arcs, the same length of the arc is preserved as much as possible, which, in stationary clocks, can be very nearly arrived at, as the only cause for the length of the arc diminishing is the decrease of the maintaining power by any additional friction of the machine.

(884.) The pendulum, although so admirable a regulator for stationary clocks, was of course totally inapplicable to those intended to be portable, and the vibrating balance, which was liable to considerable error, still continued to be the only means of governing them. Soon after this period, however, Hooke and Huygens introduced a slender spring to quicken and regulate sluggish vibrations of the balance, which has ultimately turned out to be of eminent utility. It is disputed which of these two skilful mechanics first introduced this pendulous spring. Berthould asserts, that although Hooke applied it first in a straight form, yet Huygens first adopted the

spiral shape as being most favourable to isochronism, while others are of opinion, certainly with more probability, that Hooke actually applied it in a spiral form among the twenty different methods which he stated in his Lectures at Gresham College, in the year 1664, might be used to answer the same purpose. (*Lectiones Cutlerianæ*, 1673.) Indeed, the account of the spiral springs adopted by Huygens was not published in the *Philosophical Transactions* until the year 1675, No. 112, whereas Hooke had discovered the isochronism of springs, and registered its discovery, in the year 1658.

The instruments for measuring time from this period assumed two distinct forms, viz., those governed by a pendulum, which were called clocks, and which were stationary, and those governed by the balance, termed watches, chronometers, or portable timekeepers, which, from the construction, might be transported from one place to another without materially affecting their rate of going.

As the common clocks and those for portable purposes were now totally different, both in the principle of regulation as well as in their construction, it will be proper, in pursuing the account of the progress of the improvement in these machines, to treat of them separately; and we therefore now continue the history of the pendulum clocks till we arrive at its present state, and shall then again resume that of watches, from the above period of the history to the present time.

(885.) *Construction of the common clock.*—To enable the reader to comprehend the successive inventions which have added to the perfection of clocks, it is necessary, first, to describe the common clock movements, and the manner in which the pendulum is made to act as a regulator, which, once properly understood, the nature and action of the improved means which have been introduced to increase the dominion of the pendulum will be readily comprehended. In fig. 4, plate lx., is a side elevation of a common clock without the striking machinery, which have been omitted in this figure to prevent the confusion. A A, A A are two brass plates, connected together by pillars B B, which together form a frame to afford bearing for the various axles of the machinery. The maintaining power of the clock is a weight W, which is suspended to a line, one end of which is attached to the wooden support of the clock C C, and the other passes over a pulley and is wound upon the barrel *a a*, by means of a handle which fits on the square end *c* of the axle projected through the face F F of the clock. The force exerted by the weight, of course, gives motion to the barrel, and from thence, by the toothed wheel and a pinion, to the axle *e e* of the minute hand; and, by the further intervention of the wheels and pinions, *f, g, h, i*, to the axle *j* of the second hand. To this axle the regulating power of the pendulum is applied in the following manner:

Immediately over the axle of the second hand is situated another axle *k*, having a bearing at one end in the cheek of the framework, and at the other in a projecting piece attached to the other cheek. This axle is provided with a vertical rod I, of the shape shown in the figure, having an opening in the horizontal part *m* to admit the rod of the pendulum. The pendulum consists of a weight made of a shape to expose as little resistance to the air as possible, (usually termed a *bob*,) which is attached to a vertical rod, the upper part of which terminates in and is attached to a piece of metal *o*. To the same piece of metal is attached, immediately above it, a

Mechanical
Processes.

Construc-
tion of the
common
clock.

Pl. lx.
Fig. 4.

Spring
added to
the balance.

Manufac-
tures.

slender spring *n*, terminated by a square piece of metal *p*. The upper part of the spring is introduced in a slit in the projected piece on the cheek, and made in a line with the axle of the seconds hand, and the square piece of metal, above described, resting on the sides of the slit in the pendulum, is of course suspended by the spring *n*, and free to vibrate; but the part *o* being through the opening in the branch *m* of the vertical rod *m*, the oscillation given to the pendulum is communicated to the axle *k*, situated above that of the seconds hand. Upon the axle of the seconds hand is fixed a toothed or ratchet wheel *q*, and immediately above, on the axle *k*, is a claw, termed the escapement wheel, which embraces the upper part of the wheel and allows one tooth to pass at each vibration of the pendulum. The tendency to motion of the wheel *q*, communicated from the maintaining power, exerts a pressure upon the escapement as it approaches the extent of oscillation, which permits it to escape, and, although small the pressure from the increase of velocity above that of the maintaining power, is sufficient to continue the vibration of the pendulum, which would of course otherwise in time subside. Thus this beautiful contrivance, while it receives motion from the clock, regulates its velocity, as long as the length remains unaltered, with a degree of surprising accuracy.

In order that the seconds hand may perform one revolution in a minute, the ratchet wheel *q* is made with thirty teeth, and the pinions *f*, *g*, *h*, *i* are so arranged, that one revolution of the axle *e* is made during sixty of that of the seconds hand, by means of which the minute hand will complete one revolution in an hour. The hour hand, which has to perform a revolution in twelve hours, or to move at one-twelfth the speed of the minute hand, is attached to a hollow cylinder or tube which fits upon the axle of the minute hand. To this cylinder is fixed a toothed wheel *s*, the action of which is seen in the figure: this engages a pinion *t*, revolving upon a pin or axle fixed in the cheek of the framework, which is put in motion by two equal toothed wheels, *u* and *v*, the former of which is situated on the axle of the minute hand, and the number of teeth in this wheel and pinion *s* and *t* being made in the ratio of one to twelve, the hour hand is caused to perform its revolution in the time required. The wheel *u* is not fixed upon the axle of the minute hand, in order that the hands may be set without affecting the works; motion being conveyed to it from the axle of the minute hand by means of a slender spring, which, by pressing against the wheel with a certain degree of force, causes it to revolve, and at the same time will permit the wheel *u* to be turned upon the axle without in any way straining the machinery when it is required to alter or set the hour hand. The minute hand is in a similar way permitted to turn without affecting the machinery, by making the part of its axle a hollow cone, and fitting the part to which the hand is attached within, by which a sufficient friction is obtained on the surfaces of the cones to continue the motion, at the same time the minute hand can be moved to any part of the dial without doing any injury.

(886.) *Striking part.*—Having thus described all the works of the clock whose office is that of measuring the time, we proceed next to the machinery for the purpose of striking the hours, which, although performing a less important office than the former, is composed of a greater number of parts, and is more complicated in its arrangement. This is represented in the plate in the separate fig. 5 and 6.

Striking
part.

Pl. lx.
Fig. 5, 6.

Fig. 5 is a side elevation, and fig. 6 a front elevation, with the front plate removed, the wheels being represented by single lines, which the writer considers will render the several bars and levers more distinct and more readily comprehended. *A A A A* are the cheeks of the framework to support the axles of the wheels and pinions, and *a a* the barrel to which the weight is suspended to give motion to the machinery, wound up by a square projecting part of the axle in the same manner as has been described in the clockwork. The motion of the barrel is communicated, by a system of wheels and pinions *b*, *c*, *d*, to the axle *e*, upon which is situated a fly or fan *f*, which revolves with great rapidity, and which, by the motion of the barrel being greatly multiplied by the arrangement of the wheels and pinions, acts as a governor to the motion of the machinery.

The striking machinery remains at rest until the termination of each hour, when it is put in motion by the works of the clock, and continues in motion until it has struck the number of hours indicated by the hour hand on the dial, when it again stops and remains quiescent until the next hour again puts the machinery in motion. This is effected in the following manner:—*g* is a horizontal axle extending across, and having bearings in the cheek *A A*; it has attached to it in the part extending beyond the cheek a lever *h*, shown dotted in fig. 6, which rests upon a pin fixed in the wheel *v* put in motion by the clockwork. As this wheel, as before described, is equal to the wheel *u* upon the axle of the minute hand, it of course completes one revolution in an exact hour. At the end of each hour, therefore, this lever is raised, and with it the lever *i* situated within the frame, also attached to the same axle. This lever is situated immediately under another lever *j*, attached to an axle *k*, which it raises with it, and at the same time two other levers *l*, *m*, one of which rests in a notch wheel *n n* attached to the barrel, and the other in a notch in a rim attached to the toothed wheel *c*; by this means the only preventive to the motion of the wheelwork is removed, and the action of the machinery commences: *o o* is another axle, situated parallel to the two former ones, *k* and *g*, with a lever which rests upon pins fitted into the toothed wheel *b*, seen in fig. 5. As the motion of this wheel continues, it causes the head of the hammer *H*, which is situated on a rod attached to the same axle, to recede from the bell. On the same axle is also situated a stud or short lever, which, as the receding motion of the hammer takes place, presses against a spring *s* attached to the cheek, and thus when the motion of the wheel *b* has continued sufficiently to relieve the lever from the pin, the hammer is returned with considerable force and strikes the bell *B*. The lever *l*, before described, is at this time resting by its weight upon the circumference of the wheel *n n*, which is provided with notches at distances varying in the ratio of the number of hours, one, two, three, four, &c., up to twelve. As long as the lever rests upon the circumference of this wheel no impediment is given to the motion of the machinery, but immediately it arrives at a notch it falls by its weight, the lever *m* falls into the notch in the wheel *c*, and the motion is stopped. It will thus be seen that the wheel being divided into notches at proper distances, and the fly made of such a size that the twelve blows is given while passing the longest interval, the number of hours denoted by the clock may always be announced by the striking machinery.

(887.) *Compensation pendulums.*—Soon after the

Mechanical
Processes.

Manufactures.

Compensation pendulums.

application of the pendulum to clocks, it was found that the expansion and contraction of the bar or rod materially affected the rate of going. M. Lalande found the alteration in the length of a bar of iron, forming a second pendulum, to amount to nearly 0.178 of an English inch for 30° of Reaumur's thermometer; so that being regulated in the summer, the clock would gain in winter twenty seconds a day. It became, therefore, important to astronomers to have the pendulum rod composed in such a way as to correct the expansion and contraction of the metals, and various methods have been suggested to accomplish this object.

Mercurial pendulum.

(888.) *Mercurial pendulum*.—The first pendulum which was applied to a clock on this principle was the mercurial pendulum invented by Graham, which consisted of a steel rod, the lower end of which carried a large glass jar filled with mercury, so that the expansion or contraction of the rod might be counteracted by the opposite expansion and contraction of the mercury. The construction of this instrument is represented in fig. 1 of plate lxi. where *a a* is the rod of the pendulum which is of steel, and it is formed into a frame *b* at the lower end termed the stirrup, to receive the jar of mercury *c*, which at the same time that it counteracts the effects of the downward expansion of the rod serves as the weight or bob of the pendulum. The adjustment for time is made by the piece of metal *d* which slides upon the vertical rod, and by its position determines that of the centre of oscillation of the whole pendulum, and the adjustment for compensation is made by adding to or subtracting from the mercury in the jar, which alters the relative lengths of the columns of the two metals.

Pl. lxi.
Fig. 1.

The whole length of a pendulum of this construction is about 44 inches, the expansion and contraction of which is corrected by a column of mercury of 7.5 inches in the jar. The diameter of the jar is about 2 inches, and the weight of mercury from ten to twelve pounds, which, including that of the stirrup frame and rod, makes the total weight about fourteen pounds.

The advantages which mercury presents as the means of compensation have led to many attempts at improvements in the construction of the pendulum. One evil resulting from the construction employed by Graham is, that the correction for compensation, by the addition or subtraction of mercury from the jar, causes a change of place with the index point on the graduated arc.

Reid's mercurial pendulum.
Fig. 2.

This evil Mr. Reid proposes to correct by the following construction, of which a drawing is given in fig. 2, where *A B* is the pendulum rod, *C C*, *D D*, the stirrup or frame, within which is situated a frame *E E* provided at the bottom with a horizontal plate termed the *soles*, on which the jar containing the mercury is situated, and which is provided with a cover *F*. *G* is the regulating or adjusting screw, for the purpose of correcting the rate of the clock, and *H* is the index which serves to show, by a graduated plate fixed to the inside of the clock-case, the number of degrees to which the pendulum oscillates.

If the steel rod *A B* and rods of the jar frame are lengthened by heat, the jar containing the mercury will also be lowered, and the centre of oscillation carried further from the point of suspension; but the heat which lengthens the rod will at the same time expand the mercury upwards in a greater degree, and by this means the centre of oscillation is always kept at the same distance from the point of suspension. When the rods are contracted or shortened by cold, the mercury will also be

contracted by it, and hence the lengthening or shortening of the pendulum rod by heat or cold is compensated by opposite expansions and contractions of the mercury.

(889.) *Parkinson and Frodsham's mercurial pendulum*.—The improvement we are here about to describe, although applied to the mercurial pendulum, is not necessarily confined to that apparatus only, but is a fundamental principle applicable to any pendulum whatever. Mr. Frodsham, the partner of the firm Parkinson and Frodsham, No. 1, Change-alley, well known for the many excellent chronometers they have supplied to navigators, having considered all the circumstances which attend the vibration of pendulums generally, was led to an investigation of the effect which the length and strength of the spring, by which the pendulum is supported, had upon the length of the arc of vibration, the time of oscillation, and the duration of the time the pendulum would continue to vibrate when the maintaining power was not applied. This is a point which does not appear to have been before attended to; yet when we look to the laws of pendulums, it will at once appear that it must have an influential effect. In determining the centre of oscillation, we in fact assume that those particles of the body which are nearest the point of suspension tend, by their momentum, to accelerate the motion of other particles more remote; while those near the extremity in like manner retard the motion of the particles intermediate between the extremity and the axis of suspension; but in order that these two forces may have the influence we attribute to them, it is essential that the line or rod by which they are connected should be inflexible; consequently, if a rigid bar be attached by a flexible line to a point of suspension, and be put in vibration, the motion of the system will not be the same as we contemplate in our investigation; for the particles nearest to the point of junction of the flexible and rigid line cannot have the same effect upon the more distant particles as they would have if the whole were rigid; and in like manner the more distant particles cannot affect those near the point of junction according to the laws depending upon absolute rigidity; and the consequence is that, beside the actual vibration of the whole system upon the point of suspension, the rigid part of the pendulum has an oscillatory motion about some point within itself. The action of gravity, therefore, instead of being wholly engaged during the descent in accumulating power to urge the pendulum through the ascending arc, is partly employed in correcting the position of the rod, and, consequently, *a priori*, we ought to expect that a pendulum thus supported and started to vibrate in any given arc will arrive more quickly at a state of rest than another of the same length in which this defect has not place. Now if this must necessarily happen when the pendulum is supported by a flexible line, it must also in part happen when the line is replaced by a very weak, flexible spring, which scarcely differs in its effect from the line itself; but the defect will become less and less as the strength of the spring is increased, till at length the strength of the spring is too great for the weight of the pendulum, when a diminution of the arc and time of vibration will again occur from this new cause. It seems, therefore, that a certain strength of spring is better adapted than any other in any given case for prolonging the whole time of the pendulum's motion, and that this is the proper degree of strength to employ when the maintaining power is used, because a less effect will in this case

Mechanical Processes.

Parkinson and Frodsham's mercurial pendulum Fig. 3.

Manufactures.

one required to perpetuate the oscillations. Another point is no less theoretically true, that although the arc of vibration of a pendulum, when turning on infinitely fine knife edges, is a part of a circle, it can be so no longer when suspended by a spring; and it is by no means unlikely that a certain length and strength of spring may tend much more than another to approximate the arc of vibration to that of a cycloid, and hence permit all arcs of vibration to be performed in equal times.

Fig. 3.

It was these and certain practical observations which led Mr. Frodsham to enter upon a very interesting course of experiments, and to invent a mode of suspension which, while the length of the pendulum is preserved, will allow him to select that length of spring best suited to his purpose. This contrivance is represented in fig. 3. Here it will be seen that the tube *c d*, sliding stiffly on the rod *a b*, the latter being attached to the spring, if the tube be slipped upwards or downwards, and the slip at its upper part made to embrace the spring, the length of the latter may be varied at pleasure while the whole pendulum will preserve its length unaltered. Mr. Frodsham in a letter to the author, speaking of the means of determining the best length of spring, observes, that it appeared at first a difficult undertaking; but, being determined to go through the investigation, he selected a number of suspension springs, all precisely of the same length, but each differing from the other in strength, and also a silken thread; and first suspending the pendulum by this thread, the moving power not being on, and carefully raising the bob 2° , he then left it to vibrate by its own gravity; noting the time when the arc was reduced to 1° and to $\frac{1}{2}^{\circ}$, and the whole time before it came to rest. This was repeated three times.

The next experiment was with the weakest spring, the time noted as before, and repeated also three times. In like manner the several springs were tried in succession, each gradually increasing the whole time of vibration, till at length he had the satisfaction of finding amongst them that which enabled the pendulum to preserve its state of vibration for several hours; whereas the same pendulum suspended by the silken string or weak spring came to rest in little more than an hour.

Frodsham's mercurial pendulum differs also in some other respects from the usual pendulum, where commonly the vessel of quicksilver is supported by a stirrup as we have described, and is rather difficult to be managed and adjusted by a person not conversant with clockwork. Instead of this, Mr. Frodsham has a hole in the bottom of the glass vessel, in which is fitted an iron tube; the end of this is received in a counter sink in the cover, which has also a hole in it; the suspension rod is a cylinder of steel which passes through the hole above mentioned, and the vessel is supported by a nut which screws on to the bottom of the rod, while another nut on the rod itself may be run down to press upon the cover, and thus keep every thing firm; the glass vessel is likewise elliptical instead of cylindrical, and, vibrating edgewise, is supposed to offer less resistance. The adjustment of the pendulum is, from what has been stated, very simple; to lengthen it, it is only necessary to run down the lower nut, and then again to run down the upper nut to reach the top of the glass vessel; and to shorten it, the upper nut must first be run upwards to enable the lower nut to raise the vessel. The first clock made on this principle was ordered by Mr. Barlow of

Woolwich, for the College of Virginia in America, agreeable to the wishes of the late venerable President Jefferson, who just lived to see it in its place. For the above particulars the author has been indebted to Mr. Frodsham, only such verbal alterations being made as were necessary to render it a part of the general article.

(890.) *Gridiron pendulum*.—This is composed of nine round rods, five of which are made of steel and four of brass, somewhat resembling the common gridiron, and from which it probably derived its name. A drawing of this pendulum is given in fig. 4, where the brass rods are distinguished by having a slight shade over them. These rods are adjusted in such a manner, and made of such lengths, that, notwithstanding the unequal contraction of the two metals, a motion is given to the centre of gravity in a contrary direction to that which it would have had from the use of a single rod. By making use of this form, Harrison, after a great number of experiments, composed a pendulum, of which the centre of oscillation always remained at the same distance from the point of suspension, notwithstanding the variations of heat and cold in the course of the year.

The construction of this pendulum will be readily understood from the drawing given in the figure. The outside bars *a b*, *a b*, are of steel, and are attached to the cross pieces *A B* by pins, and form the exterior frame; to the lower bar *B* is attached the bars of brass *c c*, *d d*, parallel to the former, the upper ends of which are fixed in the same manner to a cross piece *c*, made free to move between the bars *a b*, *a b*. To this piece is also attached the third pair of bars *e f*, *e f*, which are of steel, and the lower end of which terminates in a fourth cross piece *D*. This in its turn carries a fourth pair of bars of brass *g h*, *g h*, which terminate above in the fifth transverse piece *E*, to which is attached the steel rod carrying the weight or bob of the pendulum; the adjustment for the rate of the clock being effected by a screw at the lower part.

It will be seen that by this arrangement, as the expansion of the steel lowers the centre of oscillation, that of the brass has a tendency to elevate it, and thus the length of rods of the different metals being made inversely as their powers of expansibility, the distance of the centre of oscillation from the point of suspension will remain constant. The principle upon which the gridiron pendulum acts is of course the same as that of the mercurial pendulum before described, viz., that the expansion of the rod is counteracted by that of a metal having a greater expansive power acting in an opposite direction. In the former case, the correcting metal employed being of great expansive power, the height of the column is required to be but small, while in the latter, the correcting metal having an expansibility not greatly exceeding that of steel, the brass rods are required to extend a great portion of the length of the pendulum.

Although, in theory, five bars only are necessary for constructing a gridiron pendulum, nine are found requisite in practice, in order that the bar to which the pendulum is immediately suspended be equally supported on each side, to prevent the tremulous motion and bending of the bars which would otherwise take place.

(891.) *Ellicot's pendulum*.—The next pendulum of any importance it is necessary to speak of is that of Mr. Ellicot, the description of which we give nearly in his own words. It is represented in fig. 5, in which *a b*

Mechanical Processes.

Fig. 4.

Fig. 5.

Manufac-
tures.

is a bar of brass, made quite fast at the upper end by pins, and held contiguous to the rod of the pendulum which is of iron, at several equal distances, by the screws *s s*. The pendulum rod as far as the brass extends is made of the same figure; but a little below the end of the brass bar, the iron is left broader for the convenience of fixing the work to it, and is made of sufficient length to pass through the ball of the pendulum C. The holes in the brass through which the screws pass into the iron rod are made of sufficient length to permit the brass to contract and dilate freely by heat and cold under the heads of the screws: *ff* represent two strong pieces of steel or levers, whose inner centres or pivots turn in two holes drilled in the broad part of the pendulum rod, and their outer ones in a strong ridge screwed upon the same part of the rod, but omitted in the drawing, in order to exhibit the internal mechanism; *g g* are two screws entering at the edge, and working in the cavity near the centre of the ball. The ends of the screws next the rod are made of the figure shown in the drawing, which pressing with the weight of the ball against the lower arms of the levers cause the short ends to press against the brass bars at *b*. The parts being adjusted in this situation, let us suppose the rod of the pendulum and brass rod annexed to it to be elongated by heat. As the brass lengthens in a greater degree by the heat, it will force the short ends of the levers downwards, and at the same time necessarily lift up the ball, which rests on the long ends of the same levers at *ff*, to any proportion necessary, and, provided the ends of the screws press upon the levers at a proper distance from the centres or pivots, the ball will be always kept at the same distance from the point of suspension, notwithstanding any alteration the rod of the pendulum may be liable to from heat or cold. What this distance ought to be may be determined, if the difference of expansion between the brass and iron is known, for the proportion the shorter arms of the levers ought to bear to the longer ones will always be as the excess of expansion of the brass to the whole expansion of the iron.

Ellicot's
pendulum
improved
by Cum-
mings.

The correctness of the principle of this instrument, although so obvious as scarcely to require demonstration, is founded upon the supposition that the pendulum rod is perfectly inflexible, and that all the parts move without friction, in which case the operation must be perfectly smooth and uniform; but as Mr. Cummings remarks, in his excellent Treatise on Clockwork, if the pendulum rod be in any degree flexible, or friction take place in any part, which of course must always be the case in practice, the operation must be attended with a degree of irregularity of motion, which, although imperceptible to the sight, must affect the accuracy of the instrument. To remedy these evils, Mr. Cummings proposed that three bars should be made use of, one of brass and two of steel, firmly connected at one end, and held together by any determinate power towards the other; here the steel bar being situated on each side of the brass, endeavour by means of the limited power which connects them to bend it, each operating in its own way, so that they counteract and destroy each other's defects.

Pl. lxi.
Fig. 6, 7, 8.

This construction will be understood by inspecting fig. 6, 7, 8 of the plate, where fig. 6 is a front view of the bars connected together, fig. 7 a side elevation of the same, and fig. 8 a front elevation of the brass bars separate. The bars *s s*, as they move on the surface of

the intermediate bar, by the different contraction and expansion of the metals, press upon the piece of metal C in such a manner that each should have equal action notwithstanding the inaccuracies of execution, and a greater degree of regularity produced than could be attained by the two rods alone. Ellicot's pendulum, constructed in this manner, Cummings conceived to equal in many respects the gridiron pendulum, with the advantage of being more easily and accurately adjusted.

Mechanical
Processes.

(892.) *Smeaton's pendulum*.—The pendulums above described are those whose application to astronomical clocks has been most extensive; but a great number of inventions have been made to effect the same object, which, although differing in the materials and construction, the principle upon which the adjustment is effected is similar in all cases. The pendulum we are now about to describe consisted of a glass rod about half an inch in diameter and 45.5 inches long. To the upper end is fixed the pendulum spring, and to the lower a screw and regulating nut. A brass ring or tube of about an inch in length is placed so as to move easily on the lower end of the rod, having a fillet at each end, one of which being in the regulating nut, and the other supports several tubes of zinc, iron, and lead, which compose what may be called the pendulum ball. The inner cylinder, which is of zinc, is $12\frac{1}{8}$ inches in length, one-eighth of an inch thick, and made to fit easily on the glass rod, the lower end resting on the upper fillet of the brass ring. On the zinc cylinder is another of iron 12 inches long and $1\frac{1}{8}$ of an inch thick, made easily movable on the zinc tube, and with a kind of bottom to it, in which is a hole for the glass rod to go freely through. The upper end of this tube rests on a fillet on the upper end of the zinc tube, and the lower end has a fillet on its outside, on which rests a leaden tube of 12 inches long and one-quarter of an inch thick, which goes easily over the iron tube.

The action of this pendulum will thus be readily understood; the rod being made of glass, the expansion by heat is small, and is counteracted by the opposite and superior expansion of the metal cylinders, which can be adjusted of such a length that the centre of oscillation does not alter its distance from the point of suspension.

(893.) *Troughton's tubular pendulum*.—This celebrated artist, to whom Science is so much indebted for the great perfection of astronomical instruments, has turned his attention to this subject with considerable success, and has produced a pendulum very perfect in its action.

Trough-
ton's tubu-
lar pendu-
lum.

A representation of the instrument is given in fig. 15, which with the following description in the words of Mr. Troughton will enable the reader to form a clear idea of its construction and action. The rod A B is composed of a tube of brass, reaching from the bob nearly to the spring, which contains another tube within, in which are five wires so disposed as to produce together (like the wire bar gridiron of Harrison) three expansions of steel downwards and two of brass upwards, whose lengths being inversely proportional to their dilatation, destroy the whole effect that either metal would have singly. The small visible part of the rod near the top is a brass tube, whose use is to cover the upper end of the middle wire, which is here single and otherwise unsupported.

Commencing from the top, the first action is downwards and consists of the pendulum spring, a short wire 0.2 inches diameter, and a long wire 0.1, which are all of steel and firmly connected together; they reach within an inch of the centre of the hole and occupy the

Manufac-
tures.

middle line of the whole apparatus. To the lower end of the middle branch is fastened the lower end of the interior brass tube, 0.6 in diameter, which terminates a little short of the top of the exterior tube, and produces the first dilatation upwards. From the top of the interior tube are suspended ten wires, 0.1 in diameter, whose situation is in a line at right angles to the swing of the pendulum, and reach somewhat lower than the attached tube itself, which they pass through without touching, and effect the second expansion downwards. The second action upwards is effected by the exterior tube, whose internal diameter is sufficient to allow the interior tube to pass freely through it; its bottom is connected with the lower ends of the last-described wires. To complete the connection, a second pair of wires, of the same diameter as the former, and occupying a position at right angles to them, acts downwards, reaching a little below the exterior tube, having also passed through the interior one, but without touching either. The lower ends of these wires are fastened to a short cylindrical piece of brass, of the same diameter as the exterior tube to which the bob is suspended by its centre.

Fig. 9 is a section of the rod, where the three concentric circles represent the tubes, and the rectangular position of the two pair of wires round the middle one is shown by the five small circles.

Fig. 10 explains the part which closes the upper end of the interior tube; the two small circles are the two wires which are suspended from it, and the three large circles show the holes through which the middle and other pair of wires pass.

Fig. 11 is intended to represent the part which stops up the bottom of the interior tube; the small circle in the centre is the part where the middle wire is fastened to it; the others, the holes for the other four wires to pass through.

Fig. 12 is the part which closes the upper end of the external tube; the large circle in the centre is the place where the brass covering the upper part of the middle wire is inserted, and the two circles denote the fastening for the wires of the last expansion.

Fig. 13 represents the bottom of the exterior tube, in which the small circles show the fastening places for the wires of the second expansion, and the larger ones the holes for the other pair of wires to pass through.

Fig. 14 is a cylindrical piece of brass, which shows how the lower end of the wires of the last expansion are fastened to it, and the hole in the middle is that whereby it is pinned to the centre of the bob. The fastenings of the upper ends of the two pair of wires are done by screwing them into the pieces which stop up the ends of the tubes; but at the lower end they are all fixed as represented in the figure.

In the apparatus thus connected, the middle wire will be stretched by the weight of the whole, the interior tube will support at its top the whole, except the middle wire, the second pair of wires will be stretched by all, except the middle wire and interior tube, the exterior tube supports at its top the weight of the second pair of wires and the bob, and the second pair of wires is stretched by the weight of the bob only.

This pendulum is one which, from the simplicity of the arrangement, possesses considerable advantages over many of these inventions; it however possesses the disadvantage of any change of temperature not acting upon all its parts equally, or being felt by the exterior

tubes before its action can arrive at the wires in the interior, which will of course for a time affect the position of the centre of oscillation.

(894.) *Thomas Reid's pendulums.*—We are indebted to Mr. Thomas Reid of Edinburgh, the author of a late Work on clock and watch work, for many suggestions of improvements in the various parts of clock machinery, and among others the subject of pendulums has engaged his attention. One of these which he has employed in the construction of clocks consists of a zinc tube and three steel rods, the manner of arranging and fastening of which will be sufficiently well understood by the drawing, fig. 16. The action is as follows: the centre steel rod when lengthened by heat will descend with the zinc tube; but the same cause which lengthens the rod *ab* downwards will expand the zinc tube upwards, and this will carry up the two outside steel rods by which the ball of the pendulum is suspended; their expansion downwards, as well as that of the centre rod, is compensated by the upward expansion of the zinc tube. The length of the rods and of the zinc tube must of course be in proportion to the expansive ratios of the metals.

Mr. Reid has also proposed a pendulum, of which the materials employed are glass and zinc. It is composed of two tubes, the interior being of glass, and 54 inches in length; upon the exterior of this is a zinc tube of 16 inches in length, which rests on iron at the bottom of the glass tube, and supports at the upper end the ball of the pendulum. As the glass tube is expanded it will carry down with it the zinc tube; but as this will be expanded in a greater ratio, the ball of the pendulum situated at the top will retain the same distance from the point of suspension, and a perfect compensation effected.

This instrument is very simple, and probably equally effective in its motion with the last described; but its liability to fracture, attending a glass tube of great length and small diameter, will always be against its use.

(895.) *Mr. Adam Reid's pendulum.*—This differs very little from the preceding, except that the material employed in the interior rod was steel instead of glass, as proposed by Mr. Thomas Reid; but the exterior cylinder, to which the bob was attached, was zinc in both cases. The construction of the pendulum is represented in fig. 17. *AB* is the steel rod extending through the whole length, *C* the bob, supported upon the compensating cylinder of zinc *D*, which surrounds the rod *AB*, and rests upon a nut *E* of a screw tapped upon the end of the steel rod to bring it to exact time; as this expands downwards by heat, the zinc expands upwards the same quantity, so that the ball always remains at the same distance from the point of suspension.

On Wooden Pendulums.

(896.) The small degree of the expansion and contraction of the fibres of wood in the direction of their length has led to the use of this substance for the rods of pendulums, and although they are in some degree affected by temperature and by the moisture of the atmosphere, the rate of clocks constructed in this manner approaches very nearly to those with a metallic compensation pendulum. The justly celebrated Colonel Beaufoy has made a very interesting series of experiments on clocks furnished with wooden pendulums, which are given in

Thomson's *Annals of Philosophy*. He first fitted up a clock beating dead seconds, and whose motion continued while winding up, with a straight grained cylindrical deal rod, which he was on the point of rejecting from the irregularity of the rate, when it occurred to him, from the circumstance of the clock becoming much out of beat, that the great error probably proceeded

from the warping of the wood. He therefore caused the intermediate portion of the deal, from about an inch below the part where the pendulum spring is fastened to the upper part of the bob, to be reduced from a cylindrical to an elliptical shape, the transverse or longest diameter being parallel to the back of the clock, and by this means very much improved the going.

* Aug. 24, clock put forward two minutes.

† Nov. 25, clock taken to pieces and cleaned.

Manufac-
tures.

Colonel Beaufoy has given the continuation of his observations on the rate of this clock, which will be found in vol. i. and iii. of the *Annals of Philosophy*, which are equally satisfactory in their results, and confirmed his good opinion of the advantages in the use of this kind of pendulum. The success of this first

experiment induced him to try the effect of wood of greater density, and for this purpose he selected a straight grained piece of teak, which he applied to a clock, and registered the rate in the same manner as with the former pendulum, as given in the following Table.

* July 30th stopped the clock.

Col. Beaufoy's remarks.

Colonel Beaufoy remarks that, "by comparing this Table with the former, it appears that the pendulum, with a rod of heavy wood, is, in point of accuracy, inferior to the one made of light wood; the greatest daily variation of the latter being from minus 2.74" to plus 1.48", sum 4.52"; while with the other it varied from minus 2.52" to plus 9.5", sum 12.02". Colonel Beaufoy died a short time after this period, or it was his intention to have pursued these experiments with different woods, and to have thus added to the valuable store of experimental facts which have distinguished the life of this worthy and excellent man.

Ludham's pendulums.

Wooden pendulums of rather different construction have been made use of in the *Astronomical Observations*, published at Cambridge by the late Rev. William Ludham, Professor of Mathematics in that University; he has described a very neat and ingenious mode of fitting up a pendulum with a wooden rod, constructed for the purpose of preventing any gyratory motion. It was effected by having the pendulum ball of an equal mass round the centre of a round wooden rod, and by a thin flat hard steel crutch to give impulse on the hardened ends of two screws put through the rod, which screws retained the flat crutch as nearly as possible in the plane or line of the diameter of the pendulum rod, or at right angles to the middle plane of the pendulum ball. The ball was nearly of the form of a cheese, or the middle frustum of a globe. For a more particular account, see Ludham's *Observations*, page 81.

It must, however, be admitted that, although the wooden pendulum, from its simplicity and cheapness, is highly deserving of attention, it cannot be put in competition with a corrected metallic pendulum; not only from being defective in complete compensation, but from the lateral contraction and expansion of the wood from heat and moisture which causes a liability of the joints becoming loose, an evil which, although in some measure remedied by the use of varnish, has always a certain influence in pendulums of this construction.

The use of marble, talc, and other substances, for the rods of pendulums, has been attempted, but as the

experiments do not appear to have been attended with success, or, at all events, the pendulums constructed of these materials have not been brought into general use, we do not conceive it necessary to enter into any description of them, but refer the reader to the list of Works on this subject given at the end of the article.

On Clock Escapements.

(897.) The escapement is that part of the machinery of the clock by which, at each vibration of the pendulum, one tooth of the escapement wheel is permitted to pass, and is of course the means by which the pendulum influences the regularity of the clock. As the motion of the pendulum is preserved by the maintaining power, its vibrations must be, in some measure, influenced by the degree of force which it exerts; and consequently any difference in the action produced by increased friction of the axles from the congelation of the oil, from cold, or other causes, must affect, in some measure, the rate of the clock. It therefore became a great desideratum to obtain an escapement, such that the time of the vibrations of the pendulum would not be affected by any variation in the maintaining power; and a great number of inventions have been proposed to attain this object, the most important of which we now propose to lay before the reader.

In the escapement first employed, which is similar to that represented in the clock by Henry de Wyck, the teeth of the escapement wheel press against pallets situated upon an axis alternately in opposite directions, and as the pressure is continually aiding the pendulum in its vibration, any alteration in that pressure, produced by a variation of the motive force, will evidently affect the time of vibration and the rate of the clock.

(898.) The anchor escapement, which is that employed in the present day, was invented about the middle of the XVIIth Century, but the inventor does not seem to be known with certainty, although there is great reason for supposing that we are indebted to Dr. Hooke for this valuable discovery in addition to the many others

Manufac-
tures.Pl. lxii.
Fig. 1.

which he made in the Art of Horology. This contrivance is as follows: on the axis A (plate lxii. fig. 1) of the pendulum, or balance, is fixed a piece of metal, E A F, called the *crutch* by our artists, and *anchor* by the French, shown in the position which it takes when the pendulum is at rest. It terminates in two faces, B b, C c, of tempered steel, or of some hard stone, termed the *pallets*, upon which the teeth of the wheel act. These faces are made at such an angle that the teeth push them out on each side; thus B pushes the pallet to the left, and C pushes its pallet to the right. To comprehend the action, suppose the pendulum to be drawn aside to the right at Q, and then let go; it is plain that the tooth B pressing on the face of the pallet m B b all the way from m to b thrusts it aside outwards, and thus, by the connection of the crutch with the pendulum rod, aids the pendulum's motion along an arc parallel to Q P R. When the pendulum reaches R, the point of the tooth B has reached the angle b of the pallet and escapes from it. The wheel pressing forward, another tooth C drops on the pallet face C c, and by pressing this pallet outward evidently aids the pendulum in its motion from R to P; the tooth C escapes from this pallet at the angle c, and now a tooth B' drops on the first pallet and again aids the pendulum, and this operation is repeated continually.

It will be remarked that each tooth of the wheel acts on each pallet in succession, and that, during its action on either of them, the pendulum marks one vibration. The number of vibrations, therefore, during one turn of the wheel is double the number of teeth; consequently while the tooth slides along one of the pallets, it advances half the space between the two successive teeth, and when it escapes, the other tooth is just in contact with the other pallet. Should this second tooth chance to touch the pallet before the first has escaped, the wheel will advance no further, and the motion of the pendulum will be gradually stopped. For these reasons it is usual to allow one tooth to escape a little before the other reaches the pallet, and to allow a small drop of the teeth from pallet to pallet; it is, however, accounted bad workmanship to let the drop be considerable.

The pendulum is made to swing somewhat beyond the angle of escapement, for if it does not do so when the clock is clean and in good order, but stops precisely at the drop of the tooth, when it grows foul and the vibration diminishes, the teeth will not escape at all, and the clock will immediately stop.

This circumstance of exceeding the angle has also great influence on the performance of the clock, as it greatly affects the governing power of the pendulum. It is easy to see that when the face m b of the leading pallet is a plane, if the pendulum continue its motion to the right from P to Q after the tooth B has dropped on it, the pallet will push the wheel back again, while the tooth slides outwards on the pallet m. Such pallets will therefore make a recoiling escapement, resembling in this circumstance the old pallet employed with the crown wheel, one consequence of which is that it is not affected by any inequalities of the maintaining power.

According to a series of experiments made by Berthould, a clock, with a half seconds' pendulum weighing five drachms, was furnished with a recoiling escapement whose pallets were planes. The angle of escapement was five and a half degrees; when actuated with a weight of two pounds, it swung 8° and lost $15''$ per hour; with four pounds it swung 10° and lost $6''$. Thus it appears that by doubling the maintaining power, although the

vibration was increased in consequence of the greater impulse, the time was lessened $9''$ per hour, or about $\frac{1}{400}$. Although the variation in the maintaining power will never be to this extent, yet in so many wheels and pinions and axles, the power to effect the motion is so considerable that the variation produced by friction from cold would be sufficient to destroy the accuracy of a clock constructed with such an escapement.

(899.) Graham's escapement, called the dead beat escapement, from the circumstance of the seconds' index standing still after each drop, is represented in fig. 2. The acting face of the pallet a c is a plane, the tooth drops on a and escapes from c, in the middle point between the two when the pendulum is perpendicular. Beyond a the face of the pallet is an arch, the centre of which is the centre of the crutch. The maintaining power is so great as to produce a vibration of the pendulum greatly exceeding the angle of the escapement: the consequence of which is that when the tooth drops on the angle a the motion of the crutch is continued, the tooth presses upon the surface of the arch, but without producing any effort to accelerate the pendulum, and with no other retardation than that due to the friction of the surfaces.

It will thus be seen that, in this escapement, the pendulum gets its impulse in the very middle of its vibration where its velocity is the greatest, and the maintaining power only acting upon it for a short time, it will make but a trifling alteration in the time of describing the arch of vibration compared with the former escapement where the action continues nearly to the whole extent of the vibration, and, therefore, not merely from the action being for a greater length of time, but because it continues to a part of the arc where the power or dominion of the pendulum becomes very small.

The friction of the tooth of the escapement upon the arched part of the crutch is, of course, the means of impeding, in a slight degree, the motion of the pendulum, and several methods have been invented in order to avoid this evil. Berthould effects this in a very simple manner by forming the arches so as to produce a very slight recoil by describing them from a centre at a small distance from that of the crutch, but this is not so effectual as the method employed by Mr. Mudge, represented in fig. 3.

(900.) Here, instead of allowing the tooth to drop on the back of the pallet, it drops on a detent o t a, of which the part t a is part of an arch whose centre is A, the centre of the crutch, and the part t o is in the direction of the radius. This piece does not adhere to the pallet, but is on the end of an arm o, which turns round the axis A of the crutch on fine pivots, but is made to apply itself to the back of the pallet by means of a slender spring attached to the pallet and pressing inward on a pin fixed to the arm of the detent. When so applied, its arch t a makes the repose, and the part a makes a small portion of the face a c of the pallet.

The action of this escapement will be easily understood. When a tooth escapes from the second pallet by the motion of the pendulum from the right to the left, another tooth drops on the pallet (which the figure shows to be the first or leading pallet) at the angle t, and rests on a small portion t a of an arch of repose. But the crutch, continuing its motion to the right, immediately quits the arm o, carrying the pallet a c along with it, and leaving the wheel locked on the detent o t a. When, on the return of the pendulum, it enters the arch of action, the pallet has applied itself to the detent o t a, and withdraws it from the tooth; this immediately acts

Manufactures.

on the face *ac* of the pallet and restores the motion lost during the last vibration. The use of the spring is merely to keep the detent applied to the pallet without shaking: it is a little bent during their separation, and adds something of an opposing force to the ascent of the pendulum on the other side of the wheel, and accelerates its return. A similar detent, *bd*, on the back of the second pallet, performs a similar office, supporting the wheel while the pendulum is beyond the arch of escapement, and quitting it when the pendulum enters that arch.

This is certainly a very considerable improvement; friction is almost annihilated by transferring it to the pivots at *A*, so that in the excursions beyond the angle of escapement it seems almost entirely free. Indeed, some artists have further reduced the friction of the pivots at *A* by making the arm of the detent a spring of considerable thickness, except near *A* where it is made very thin and broad; but it does not appear that this construction, although easily executed and susceptible of great precision and steadiness of action, is much practised. A part of the friction still remains which cannot be removed, namely, that which occurs while the arch *t a* is drawn from between the tooth and pallet, and, in fact, something more must be overcome here; for the tooth is apt to force the detent outward, unless the part *t a* be a little elevated at its point *a*, like a claw above the concentric arch, and the face of the tooth be made to incline forward so as to fit the shape of the detent. This will consume some force when the momentum of the pendulum is at its maximum, and should the clock be foul and the excursions beyond the escapement very small, this disturbance must be exceedingly pernicious. Dr. Robison also points out the following objection, *viz.*, that during the whole excursion beyond the angle of escapement there is a new force of a spring acting on the pendulum, which deviates considerably from the proportions of the accelerating power of gravity. It does not commence its action till the detent separates from the arm of the crutch, and then the spring of the detent acts as a retarding force against the excursion of the pendulum, now on the other side, bringing it sooner to rest and then accelerating it in its way back to the beginning of the arch of escapement.

(901.) Very similar to this (at least in the excursion beyond the angle of escapement) is the construction of Mr. Cummings, and it has the same defects. His pallets are carried in a similar manner as in the one described by the crutch: the detents press on them behind by their own weight only, and therefore when the tooth is locked on the detent of one pallet, its weight is taken off from the pendulum on that side, and the weight of the detent on the other side opposes the ascent and accelerates the descent of the pendulum.

Mr. Cummings executed another escapement consisting, like the above, of a pallet and detent; but the manner of applying the maintaining power is different in principle from any yet described. It is exceedingly ingenious, and seems to do all that is possible towards removing every source of irregularity in the maintaining power, and every obstruction to free motion arising from friction and oil in the escapement. Fig. 4, plate lxii., exhibits as much of this escapement as is necessary for explaining its general action; but those readers who wish to see all the minutiae of the construction must have recourse to the Work written by the author, as the complexity of the parts requires a more minute representation than our plan admits of. *A B C* is the

escapement or swung wheel, *D E* the pallets separately movable on the axis of motion, and having each a little ball or weight *H* and *I* supported by horizontal arms. Each pallet with its attached weight is separately movable from the other round its respective axis of motion, so that when one is raised by the wheel the other remains at rest. *F* and *G* are two detents firmly attached together like the ordinary pallets, or a common dead beat or recoil escapement, and are fixed to a cylinder of brass *P* that surrounds the two axes of motion of the pallets, which are in the same straight line, but separated from each other at the middle of the cylinder, where there is a partition that bears the interior pivot of one axis and the exterior one of the other; the crutch of the pendulum is also fast to the cylinder, so that the two detents and crutch move together with the cylinder without the motion of either pallet, and each pallet can move separately without the detents and crutch. *M* is a weight to counterpoise the detents and crutch in any position given them; and *n o* are two pins carried by the pendulum that project far enough to fall alternately in the way of the arms which carry the balls *H I* as the pendulum vibrates.

To explain the action of the escapement, let us suppose the different parts in the position shown in the figure, where the lever of the detent *G* is hid behind the lever of the pallet *E*, but may be conceived to be parallel to it; and the pallet *D* having been previously lifted from its quiescent position, where its point rested on the rim near the foot of the tooth *A*, then if we conceive the pendulum moving from right to left with the ball *I* urging the pin *o* attached to an arc fixed to the pendulum, the vibration is aided by the gravity alone of this ball. The arc that bears the pins *n* and *o* has a contrivance, not seen in the figure, for unlocking the detents at the moment when either of the pins bears against its ball. Conceive now the pin *n* brought into contact with the arm of the ball *H* by the motion of the pendulum; the detent *F* is unlocked and the tooth *A* of the wheel quits the end of the pallet *D*, the ball *H* now acts by its gravity on the pin *n* and descends at the same time aiding the returning vibration, while the pallet *D*, united to the arm of the ball *H*, descends also towards the wheel; but as soon as the pendulum first began its original vibration, the pin *o* was withdrawn from the pressure of the ball *I* by means of the attached pallet *E* falling on the tooth *C* of the wheel, so that all the latter part of the vibration was free; this pressure of the pallet *E* on the tooth *C* diminished the pressure of the tooth *A* on the detent *F* at the instant of unlocking.

The wheel, now in motion by the action of the maintaining power, goes on till the tooth *C*, acting on the pallet *E*, raises it outwards, together with its attached ball *I*, till the detent *G* stops the wheel's motion, when all the parts are at rest till the pendulum nearly finishes its returning vibration, and then its pin *o*, meeting with the elevated arm of the ball *I*, presses against it and concludes the vibration; at the moment the pressure is felt the contrivance we have mentioned above unlocks the detent *G* and allows the tooth *C* to escape; in the meantime the ball *I*, by its gravity, urges the pendulum for a short time, while the tooth following *A* meeting with the pallet *D* raises it and the ball *H* a second time, the following tooth comes in the way of the pallet *E* and stops the further action of the ball *I* on the pendulum, which now vibrates, as before, free, till its pin *n* again meets with the arm of the ball *H*, when the same

Cummings's escapement.

Fig. 4.

Manufac-
tures.

operation is repeated, and thus the weights H and I are alternately raised by the wheel, and then alternately act for a short time on the pendulum at the commencement of each vibration, so that gravity alone is, properly speaking, the maintaining power of the pendulum; and whatever may be the motive force it never affects the motion of the pendulum, but only raises the balls, which afterwards act alternately by the influence of gravity. Thus whatever may be the effects of oil, friction, wear, &c., on the action of the wheelwork, as it has no immediate connection with the pendulum except during the instant of unlocking the detents, these effects are almost entirely avoided as they regard the pendulum or regulating part of the motion.

The greatest objection in this construction is, that the additional gravity commences instantaneously, and also ceases instantaneously, and at a part of the vibration where the sudden exertion of any force is least favourable for aiding the simple gravity of the pendulum; it is also difficult of execution from being constituted of a great number of parts, and does not appear to have been found in practice superior to the simple dead beat.

Harrison's
recoil
escapement,
Fig. 5.

(902.) Notwithstanding the seeming superiority and great character which the dead beat escapement has long acquired over the recoiling one, the latter had its partisans; among whom were artists and amateurs possessed of the first-rate talents—Professor Ludham of Cambridge, Berthould, Smeaton, and others. Harrison also always rejected the dead beat; he constructed a clock with an escapement on the recoiling principle, invented by himself, which went for fourteen years without being touched, and during that time did not vary one complete second from one day to another, nor even deviated half a minute by accumulation from equable motion. We have given in fig. 5 a representation of this escapement; *g D o* is the swing wheel, of which *M* is the centre and *a* is the verge or arbor of the pendulum, provided with two short arms, *a b*, *a c*. A slender rod *b e* turns on fine pivots in the joint *b*, and has at its extremity a hook or claw, which takes hold of a tooth *d* of the swing wheel, when the pendulum moves from the right to the left. This claw, when at liberty, stands at right angles, or at least in a certain determinate angle with regard to the arm *a b*, and when drawn a little from that position it is brought back to it again by a very elastic spring. The arm *a c* is furnished with a detent *c f*, which also, when at liberty, maintains its position on the arm by means of a slender spring.

Let us suppose the tooth *d* is pressing on the claw *e* while the pendulum is moving to the left. The joint *b* yields, by its motion round *a*, to the pressure of the tooth on the claw, by which the angle *a b c* opens a little. In the mean time the same motion round *a* causes the joint *c* of the detent on the other side to approach the circumference of the wheel, and the tooth *g* at the same time advances; they meet, and the point of *g* is lodged in the notch under the projecting piece *f*; when it is evident that any further motion of the point *e* round *a* must push the tooth *g* a little backwards by means of the detent *c f*; it cannot come any nearer to the wheel because the point of the tooth stops the heel *f*. The instant the part *f* recoils from the tooth *g*, the tooth *d* is withdrawn from the claw *e*, which flies out by the action of its spring and resumes its position at right angles to *b a*; and the wheel being now free from the claw is pushing at the detent *f*. The pendulum having finished its oscillation

to the left (in which it causes the wheel to recoil by means of the detent *f*) returns towards the right, the wheel advances, and by pressing on *f* aids the pendulum through the whole angle of escapement. By this motion the claw *e* describes an arc of a circle round *a* and approaches the wheel till it takes hold of another tooth, viz., the one following *d*, and pulls it back a little, which immediately frees the detent *f* from the pressure of the tooth *g*, and it flies out a little from the wheel resuming its natural position by means of its spring; soon after the motion of the pendulum to the left ceases and it returns, being aided by the part *d* pulling forward the hook *e*.

Friction is nearly avoided in this escapement and oil entirely. The motion is given to the pendulum by a fair pull or push, and the teeth of the wheel apply themselves to the detents without rubbing. There is no drop, and the escapement makes no noise, and is for this reason called by the artists a silent escapement. By properly disposing the arms *a b*, *a c*, and disposing the pallets on the circumference of the wheel, the law by which the action of the wheel on the pendulum is regulated may be greatly varied so as to harmonize with the action of gravity.

It is, however, a recoiling escapement, and one, Dr. Robison remarks, of the worst kind; for the recoil is made at the very confines of the vibration, where every disturbance of the regular cycloidal vibration occasions the greatest disturbance to the motion. Yet this clock kept time with most unexampled precision, far excelling all that had been made before.

From this fact we may learn that the governing power or dominion of the pendulum is so great, that the action upon it from the maintaining power is not sufficient to influence, in a great degree, the irregularity of the vibrations; and that in a well-made clock with a heavy pendulum, any one of the escapements we have described, executed with pallets of agate and a wheel of hard steel, and the pendulum rod suspended, there will be hardly any difference observed in their performance; and thus has arisen the difference of opinions and controversies on the recoiling and dead beat escapement.

(903.) *Striking part of a clock.*—In the commencement of this article has been described one of the methods by which a clock is made to strike the hours indicated on the dial; but in modern clocks different means are employed, which, although rather more complicated and difficult of execution, have considerable advantages over the former, and are consequently generally preferred. If a clock provided with the count-wheel striking part be made to strike between the hours, by raising the detent it will strike the next following hour, and if again raised the next hour, and so on, successively increasing a stroke each time the machinery is put in motion; but in the latter method, the clock will continue to repeat the hour indicated on the dial for any number of times it is made to strike. This is a considerable advantage, as in the night the time may be known by simply pulling a string connected with a detent in the machinery; while a corresponding evil exists in the old striking part, from the inconvenience which results if, by any accident, the detent be raised so as to permit the clock to strike.

In plate lxii., fig. 6, is given the elevation of the front Pl. lxii. plate of a spring clock provided with this machinery; it exhibits the most important parts connected with the

Modern
striking ma-
chinery.
Fig. 6.

Manufactures.

striking; the position of the remaining parts, which are hid from view, are shown by dotted lines. The wheels A B C, with their respective pinions, convey the motion from the main wheel to the fanner D, which regulates the velocity by its resistance to the air. They are situated between the two plates of the clock frame, and are consequently shown dotted in the figure. The wheel A has eight pins, which lift the cross piece *e* of the arbor E eight times in each revolution of the wheel A. These elevations of the piece *e* occasion as many portions of a revolution of the arbor E, which has its pivot projecting behind the frame, and carries upon it the hammer E', which is consequently raised every time a pin of the wheel A moves the piece *e*. F is a long and powerful spring called the hammer tail spring, attached to the back part of the frame, which presses at its upper extremity under a cross pin passing through a hole in the arbor E, near the face of the back plate; so that when the hammer is raised at any time, the spring F urges it back again with a strong blow and makes it strike the bell, which is usually situated in these descriptions of clocks behind the frame, but is shown in a different position in the figure, in order that the action of the hammer may be more distinctly seen. To prevent the blow being too strong, a counter spring G is attached to the contiguous pillar of the framing, which breaks the violence of the blow and makes the hammer return smartly to its position when the blow is made; this spring also serves as a guard, in case the stroke of the hammer should be made when the bell is taken off at any time.

It will thus be seen that when the detent is removed, so as to permit the motion of the striking machinery, a number of blows will be given to the bell at intervals, governed by the resistance of the flyer or fan D. We have now to explain in what manner the machinery is put in motion at the end of each hour, and how the number of blows of the hammer is made to agree with that indicated by the hand on the dial. To the twelve-hour wheel is attached, by pins, an indented spiral piece of metal *a*, called the snail, (the shell of which it resembles in some measure,) which snail consequently revolves likewise in twelve hours; it has twelve steps upon the circumference, each of which subtends an angle of thirty degrees, so that, whether near to the centre of motion or remote from it, it is exactly the measure of an hour's motion of the twelve-hour wheel; *b* is a piece of steel called the rack, which is movable on a pin or stud at the lower angular point, near which the horseshoe spring *c*, called the rack tail spring, presses, to keep a pin on the remote end of this tail against the indentation or step of the snail, which happens to be contiguous to it; this pin is hid from the sight, but the place may be seen from the extremity of the tail where it is inserted. Above the rack is a horizontal steel bar *d f g*, movable round a stud *a d*, which is called the hawk's bill, from the bill or angular piece at *p* which engages the teeth of the rack. The piece *i i*, fixed to the projected part of the pivot of the wheel B near its lower extremity, and revolving with it, gathers up a tooth of the rack at each revolution, on which account it is called the gathering pallet; the catch of the hawk's bill, having a contrary slope, gives way in the mean time and comes back again by its own gravity. The wheel A has sixty-four teeth and eight pins, and its pinion has eight leaves, which therefore revolves once every time that the hammer of the bill is lifted, and as the gathering pallet takes

up a tooth of the rack at each revolution of its arbor, a tooth of the rack is taken up at each stroke of the hammer when the striking part is in motion. The angular piece *j k l* is called the warning piece; it is movable round an arbor at the angular part, and its lower end *l* falls in the way of a pin in the small hour wheel *m*, and its bent end *j* passes through an aperture *n* in the front plate of the frame, and is presented to a pin in one of the crosses of the wheel C of the striking movement within the plate, so as to restrain its motion when required to be in a quiescent state.

The action of the different parts is as follows: when the hawk's bill is lifted from the teeth of the rack by the pin upon the hour wheel, the spring *c*, pressing against the tail, makes it fall back till it meets with some obstacle to arrest its motion; that obstacle would be the pin *p* in the front plate, if there were no other interposed before it had fallen so far; but if the snail is in any other position than that wherein its indentation nearest the centre is contiguous to the pin on the rack tail, the tail pin on the rack will fall upon the edge of the snail before the rack has fallen back to the pin *u*, and all the teeth will not pass the hawk's bill, but only so many as there are indentations or steps from the remote angular point of the snail, to the step on which the tail pin rests; in the present position in the plate the tail pin is resting on the sixth step of the snail, which denotes that six strokes will be given by the hammer, or that six teeth of the rack are to be gathered up by as many revolutions of the hawk's bill; but it may be perceived that only five teeth remain to be gathered up by the rack; hence we know that the clock is in the act of striking, and has struck one out of the six. The pin in the hour wheel has just raised the warning piece and permitted it to go again; the clock will therefore continue to strike till the upper end of the gathering pallet falls on the projected pin *p* of the rack, which will be as soon as the last tooth of the rack is drawn up to the hawk's bill, in which situation the wheel *c* cannot revolve any further till another hour has elapsed.

When another hour has passed, the pin on the hour wheel will again elevate the warning piece *l*, the bent end of which will be raised out of the way of the pin of the wheel *c*, and the fly will run on a revolution or two with a whirling noise, *i. e.* the clock will give warning; but the end *g* of the hawk's bill has not been raised far enough by the end *j* of the warning piece to permit the catch *i* to clear the teeth of the rack, therefore the rack cannot yet fall back; presently, the hawk's bill is raised high enough by the continuation of the motion of the pin of the report wheel *m* and the rack falls back, till its tail pin rests on the seventh step of the snail, which has arrived during the interval of the hour contiguous to the pin on the rack tail, and there are in consequence seven teeth of the rack past the catch *i*, and therefore the hour seven will be struck before the tail of the gathering pallet falls again on the pin *p* of the rack and stops the striking; when at the same time the bent of the warning piece catches the pin of the wheel *c* and stops the motion of the fly.

It will thus be seen that the number of hours struck by the hammer will be regulated by the position of the snail, which revolving once in twelve hours, and being divided into twelve steps or indentations, each subtending an equal angle from the centre, a new step will be presented to the pin of the rack tail at the end of each hour, and an additional blow given by the hammer. It

Mechanical Processes.

Manufac-
tures.

will also be seen, that, as the snail or regulator of the number of strokes is not attached to the striking movement as in the count-wheel machinery, the striking may be repeated any number of times during the interval of an hour, or the passing of one step of the snail, and will indicate each time the same number of hours, so that the snail being placed in such a position with respect to the rack tail that a fresh step is presented to the pin the instant before the pin on the wheel elevates the warning piece, the passing hour will always be struck any time the machinery is permitted to work, until the instant the new hour commences.

This striking part may, therefore, be readily converted into repeating mechanism; and the drawing given in the plate, taken from a clock in which the additional parts necessary to effect this are added, we have chosen in order to illustrate the principle upon which the repeating watches and clocks are constructed. A lever $q q$ is situated in front of the plate, one end of which engages a pin on the warning piece, and the other extends beyond the case of the clock, and is provided with a line which is at all times accessible; the lever turns upon a pivot or stud at r , and is provided with a spring to return to its original position; it will thus be seen that, as often as the string is pulled, the catch will be raised clear of the rack, and the striking mechanism will be put in motion and will indicate, however often repeated, the strokes of the current hour. It still remains to explain the three-armed piece $s t u$, which is called the strike or silent, by the use of which the clock may be made to strike at any part of the hour, or the striking mechanism totally detached from the clock's movements so that the clock will revolve from hour to hour without striking. This piece is made movable on a socket rivetted to the end u of one of the arms, round a stud in the front plate of the frame, and as the socket has scarcely any shake or lateral motion, the other two ends s, t move always in the same plane. At the end marked s is a pin which projects beyond the upper part of the face or dial of the clock, so that it may be moved to the right or left at pleasure, when the glass door is open; the end t has a slope like a wedge on that side which is next to the plane of the plate frame, and the end of the arbor situated within the frame on which the warning piece is fastened projects so far as to touch the inclined plane; this arbor of the warning piece has some shake or is seen to move in the direction of its length. Its posterior pivot passes between the prongs of a forked spring, which, resting against its shoulder, pushes it close to the interior side of the front plate of the frame where a similar shoulder stops it.

When the pin at s is pushed to the right, the wedge of the end t pushes the arbor back notwithstanding the forked spring, and the end l of the warning piece being carried with its frame nearer to the arbor than it otherwise would be, falls in the way of the pin of the hour wheel, and the clock consequently strikes the hour regulated by the snail, and if left in that position, the clock will again strike at the end of one hour; but if the pin at s of the strike or silent is pushed to the left, the end t is withdrawn from the pivot of the arbor on which the warning piece is fast, the spring in the frame pushes it forward so far that the end of the warning piece is clear of the pin of the hour wheel, which continues to revolve from hour to hour completely detached from the mechanism of the striking part.

This ingenious striking machinery, although an invention of long standing, does not appear to have been improved upon, and is still continued to be preferred. Among the many inventions appertaining to clockwork which have been rewarded by the Society of Arts will be found several on the striking mechanism; but as they do not appear, from what we are able to learn, to be generally adopted, we have not entered into a description of them, but beg to refer the reader to vols. xxi., xxix., xxxv., and xxxviii., of the Society's *Transactions*. Striking machinery of very ingenious construction is also described in several of the Works enumerated at the end of this article.

Mechanical
Processes.

Construction of Watches.

(904.) Having in the preceding pages explained the construction of that description of timekeepers whose governing power is a pendulum, termed clocks, we return again to that part of the history of these inventions when the pendulous properties of the spring were discovered, and when portable clocks or watches assumed a form and dimensions totally different from that of the clock. Although the form and arrangement of these two instruments are so very different, the principle upon which the regulation is effected is the same in both, the office of the weight or maintaining power being supplied by a spring, and the vibrations of the pendulum by those of the balance and spring. These latter maintaining and regulating powers are equally perfect with those of the clock in a theoretical point of view, but are much inferior in their action; and although chronometers have been brought to a degree of perfection truly surprising, they will probably never equal in their performance a well-made clock; a conclusion which one is not only led to by experience, but which simple reasoning on the nature both of the maintaining and regulating power will readily point out. In the first place, the power of a spring must be subject to irregularities as it relapses, which, although compensated for in a great measure by the action of the fusee, cannot possibly be entirely corrected, and certain irregularities from this cause will creep in which are additional to those of variations of friction to which a clock is subject. Again, the regulating power of the balance has much less control or dominion than that of the pendulum, and is, consequently, less able to correct the same irregularities; and although by the beautifully contrived escapements of Earnshaw and others its natural vibrations are but little interfered with, yet in making a comparison of the performance of these two machines, where an equal degree of skill and workmanship have been displayed, the clock must necessarily, from the superior dominion of the pendulum, approach nearest to true time.

Notwithstanding, however, the clock has the precedence of the watch or chronometer in point of its perfect measurement of time, still its uses, though highly valuable to Science generally, and to Astronomy in particular, are far less important than those of the chronometer, the use of which is so practically valuable to the sailor, who by its aid is able to traverse the ocean with a degree of confidence and safety which could not be arrived at by any other means.

Before we proceed to describe the successive inventions which have produced the present improved state of this instrument, it will be necessary to give a drawing and explanation of the construction of the common

Construc-
tion of
watches.

Manufactures. watch which has remained with the same escapement and nearly in the same shape as when first invented.

Description of a common watch. Plate lxxiii, fig. 1 and 2, is the plan and elevation of the works of a common watch, the position of the different parts in the elevation being a little deviated from that in which they would be seen in viewing the watch, in order that their action may be more clearly understood, but the position and manner of arrangement will be readily perceived from the plan. The moving power is a spiral steel spring which is coiled up close, by a tool used for the purpose, and put into a brass box called the barrel; the spring has a hook at its outer end which is put through a hole in the side of the barrel and rivetted, and the inner end has an oblong opening cut through it to receive a hook upon the barrel arbor. This arbor extends through the bottom of the barrel, and is made square to hold a worm or tooth wheel *d*, which is turned round by a worm and serves to adjust the action of the spring to that of the fusee; the end of the arbor projects beyond this and is attached by a pivot into the lower or face plate *A* of the watch; the top of the barrel has a cover put over it, through which the pivot of the arbor projects and works in a socket in the upper plate *D*.

The barrel thus mounted has a steel chain *a*, hooked to the upper part and coiled round, the other end of which is attached to the fusee *E*. It is thus evident that when the fusee is turned by the watch key it will wind the chain off the barrel on itself; and, as one end of the spring is fastened to the barrel and the other end to the arbor, (which is prevented from turning by the worm wheel beneath,) the spring will be coiled up in a smaller compass than it was before, and by its reaction will, when the watch key is taken off, act on the fusee and exert a force to turn the movements of the watch. The fusee has a spiral groove cut round it in which the chain lies; this groove is cut by an engine in such a manner that the chain shall pull from the smallest part of the fusee when the spring is wound up, and acts with its greatest force, and gradually increases in size as the spring unwinds and acts with less power, so that the motive power of the watch may be always the same. For the action to be always equal, the strength of the spring, at any state of unwinding, should be inversely in proportion to the radius or diameter of the fusee, which is the lever by which it acts. This is effected by adjusting the position of the spring with respect to the fusee by the worm *b*, which turns up the spring and causes it to act with greater force. By this adjustment the power of the spring at the commencement and completion of its action, being made in proportion to the respective diameters of the fusee upon which the chain is coiled, the intermediate states of the spring, from the particular curve given to the fusee, will be exactly in the correct proportion, and an equable action on the works produced.

The fusee has a ratchet wheel at the lower end which engages a click fixed in a hollow cut in the great wheel *e*, in order that when the watch is being wound up the fusee may slip round without the wheel, but that when, by the action of the spring, it is turned in the contrary direction, it engages this wheel, and thus puts the works of the watch in motion. The great wheel has forty-eight teeth on its circumference, which engage and turn a pinion of eight teeth fixed on the same axle with the centre wheel *g*, which has fifty-four teeth, and engages a pinion of six leaves on the axle of the third wheel *h*: this wheel has forty-eight teeth and turns
